To clarify the function of cyclin A2 in colon homeostasis and colorectal cancer (CRC), we generated mice deficient for cyclin A2 in colonic epithelial cells (CECs). Colons of these mice displayed architectural changes in the mucosa and signs of inflammation, as well as increased proliferation of CECs associated with the appearance of low- and high-grade dysplasias. The main initial events triggering those alterations in cyclin A2-deficient CECs appeared to be abnormal mitoses and DNA damage. Cyclin A2 deletion in CECs promoted the development of dysplasia and adenocarcinomas in a murine colitis-associated cancer model. We next explored the status of cyclin A2 expression in clinical CRC samples at the mRNA and protein levels and found higher expression in tumors of patients with stage 1 or 2 CRC compared with those of patients with stage 3 or 4 CRC. A meta-analysis of 11 transcriptome data sets comprising 2239 primary CRC tumors revealed different expression levels of *CCNA2* (the mRNA coding for cyclin A2) among the CRC tumor subtypes, with the highest expression detected in consensus molecular subtype 1 (CMS1) and the lowest in CMS4 tumors. Moreover, we found high expression of *CCNA2* to be a new, independent prognosis factor for CRC tumors.

Introduction

Colorectal cancer (CRC) is one of the leading causes of malignancy-related death worldwide, with an increasing incidence (1). The disease status of patients can be classified according to histologic tumor grade (differentiation) and anatomic extent of the disease (i.e., tumor/node/metastasis [TNM], stages 1–4), which describes tumor growth into the wall of the rectum or colon (stage 2), involvement of regional lymph nodes (stage 3), and metastatic spread to other organs (stage 4) (2). Once metastasis has developed, 5-year survival rates following surgery are below 10% (3). Also, adjuvant chemotherapy after surgical resection for stage 3 CRC and high-risk stage 2 tumors (i.e., tumors with poor differentiation, T4 classification, lymphovascular invasion, or perineural invasion) increased patients' survival rates, but many will relapse or develop distant metastases (4, 5). Thus, there is an urgent need to better understand the molecular changes leading to the development of CRC to identify novel therapeutic strategies.

An important risk factor for CRC development is inflammation. Patients with early-onset chronic inflammatory bowel disease (IBD)

and widespread manifestation (i.e., pancolitis) have a higher probability of developing CRC (6). Furthermore, inherited mutations have been identified for 5% of patients with CRC, with diseases traditionally divided into polyposis syndromes, such as the familial adenomatous polyposis (FAP) and nonpolyposis syndromes like Lynch syndrome, also known as hereditary nonpolyposis colorectal cancer (HNPCC) (7). Sporadic CRC is a molecularly highly heterogeneous disease. Research teams from different institutions recently performed a meta-analysis of the different reported subclassifications to define the existence of 4 distinct gene expression-based subtypes (consensus molecular subtypes [CMSs]), i.e., immune (CMS1), canonical (CMS2), metabolic (CMS3), and mesenchymal (CMS4) (8). Each CMS has a unique biology and gene expression pattern (8), thus providing a framework for designing subtype-specific and personalized treatments. Indeed, CMSs have different clinical features including prognosis and response to therapies, with CMS4 having the worst prognosis.

Cyclin A2 is an established regulator of cell proliferation and has been used for molecular diagnostics as a proliferation marker (9). However, several studies suggest that cell-cycle regulators can exert additional functions, well beyond cell-cycle control (10–16). For example, the cyclin CDK inhibitors p21, p27, and p57, as well as cyclin D1, have been found to be involved in the control of apoptosis, transcription, cytoskeletal dynamics as well as cell migration (12–13, 16)

Figure 1. Cyclin A2 deletion leads to epithelial changes in the colon mucosa and inflammation. (A–C) Immunostaining for cyclin A2 (A), F4/80 (B), and IL-6 (C) of the indicated parts of colons from control (*Ccna2^{fl/fl}*) and constitutive (*VilCre Ccna2^{fl/fl}*) cyclin A2-deficient mice. Scale bars: 100 μ m. Original magnification, $\times 2$ (enlarged insets).

We previously described a role for cyclin A2 in the regulation of cell migration and invasion (17–19). More specifically, we found that deletion of cyclin A2 in a murine mammary gland epithelial cell line (NMuMG) induces epithelial-mesenchymal transition (EMT) and increases invasiveness in vitro as well as in vivo in an avian embryo model (18, 19). This concurs with a recent report that identified cyclin A2 as a key regulatory

component in EMT and metastasis of lung cancer cells by modulating the TGF- β signaling pathway (20).

Few studies have investigated the role of cyclin A2 in tumor development in vivo using genetically altered mice. One study described the generation of mutant mice with reduced cyclin A2 expression. These mice displayed spontaneous tumor development, in particular in the lung, and were also more susceptible to

chemically induced skin cancer (21). On the other hand, tissue-specific cyclin A2 inactivation in the liver was shown to impair hepatocellular carcinoma development and recapitulated the phenotype observed in absence of cyclin-dependent kinase 2 (CDK2) (22). These observations point to a tissue-specific role of cyclin A2.

We previously reported lower cyclin A2 expression in hepatic metastases compared with primary tumors derived from the same CRC patients (17). This prompted us to investigate the role of cyclin A2 in colon homeostasis and carcinogenesis using cell type-specific KO mice.

Results

Cyclin A2 depletion in the colon induces epithelial changes in the mucosa and inflammation. We established 2 mouse models to study the function of cyclin A2 in colon homeostasis and CRC development by using the previously established conditional cyclin A2 (*Ccna2^{fl/fl}*) strain that is based on the Cre/LoxP system (23). Constitutive deletion of cyclin A2 in the intestinal epithelium was achieved by crossing cyclin A2 conditional-KO mice with the *villin-Cre* mouse strain (*VilCre*). Expression of Cre under the *villin* promoter was shown to be active in intestinal epithelial cells (24). In addition, we crossed *Ccna2^{fl/fl}* mice with the inducible Cre mouse strain *villin-CreERT2* (*VilCreERT2*), in which *Ccna2* is excised upon intraperitoneal injection of tamoxifen (24).

We validated cyclin A2 loss in colonic crypts of *VilCre Ccna2^{fl/fl}* mice by immunohistochemical analysis (Figure 1A). For this, we analyzed the distal region, close to the anus, as well as the proximal region, close to the cecum (Supplemental Figure 1A; supplemental material available online with this article; <https://doi.org/10.1172/JCI131517DS1>), since biological and clinical differences for both segments are well established (25). In both regions, we detected cyclin A2 expression in epithelial cells of the lower part of the crypts in control mice, whereas cyclin A2 expression was undetectable in colonic crypts of cyclin A2-KO mice (Figure 1A).

During the immunohistochemical analysis of cyclin A2 expression, we noted epithelial changes in the colonic crypts as well as architectural alterations in the mucosa of cyclin A2-deficient mice (Figure 1A and Supplemental Figure 1B). We also detected immune cell infiltration in cyclin A2-deficient colons. The immune cell infiltrates had morphological characteristics of macrophages and were immunostained using the macrophage marker F4/80. This revealed an increased number of F4/80⁺ cells, approximately 2-fold in constitutive (Figure 1B and Supplemental Figure 1C, left panel) and 1.5-fold in induced (Supplemental Figure 1C, right panel) cyclin A2-deficient colons versus normal ones. Macrophages can be important producers of the proinflammatory cytokine IL-6 (26), and, in fact, IL-6 was detectable in the stroma of cyclin A2-deficient colons but not in those of control mice (Figure 1C). Taking this one step further, we tested whether the infiltrating macrophages can be assigned to the M1 or M2 subtype, which have been attributed anti- and protumoral functions, respectively (27). Immunostainings for the M2 markers YM1 and TGF- β showed that colonic stroma of cyclin A2-deficient mice harbored predominantly M2-polarized macrophages (Supplemental Figure 1D).

Moreover, approximately 15% of male and 10% of female *VilCre Ccna2^{fl/fl}* mice developed rectal prolapses within the first 3 months of age, which can be considered an indicator of inflammation (28).

Taken together, cyclin A2 deficiency in colonic epithelial cells (CECs) induces epithelial and architectural alterations of colonic crypts as well as different signs of inflammation.

RNA-Seq analysis reveals a prominent altered expression of genes involved in the cell cycle, the mitotic process, chromosome segregation, and DNA double-stranded break repair. To gain insights into the molecular traits of *Ccna2*-mutant mice, we performed RNA-Seq using CECs isolated from the proximal colon of *Ccna2^{fl/fl}* mice ($n = 4$) and *VilCre Ccna2^{fl/fl}* mice ($n = 4$) at 4 weeks of age. At this age, *VilCre Ccna2^{fl/fl}* mice already displayed visible distortion of the crypt architecture that was validated by immunohistochemical analysis of the distal region of the colons used in this experiment.

Notably, the RNA-Seq experiment validated the deletion of exons 2 to 7 of the *Ccna2* gene and thus the efficient inactivation of cyclin A2 in CECs of *VilCre Ccna2^{fl/fl}* mice (Supplemental Figure 2A). Supervised analysis of the RNA-Seq data identified 469 upregulated and 640 downregulated genes in *VilCre Ccna2^{fl/fl}* mouse samples versus *Ccna2^{fl/fl}* mouse samples (fold change >2, adjusted P value $|\text{FDR}| > 0.05$) (Supplemental Table 1). Pathway analyses of the most altered genes revealed that the most significant biological functions associated with the genes upregulated in *VilCre Ccna2^{fl/fl}* mice were related to the cell cycle (nuclear division and mitosis, regulation of the mitotic cell cycle, $P < 2.79 \times 10^{-3}$ to 1.15×10^{-12}), cellular assembly and organization (chromosome segregation, chromatin segregation, $P < 3.01 \times 10^{-3}$ to 1.80×10^{-9}), as well as DNA replication, recombination, and repair (double-stranded break repair [DSB] and homologous recombination, $P < 3.01 \times 10^{-3}$ to 1.80×10^{-9}) (Supplemental Tables 1 and 2 and Supplemental Figure 2B). In line with this, the analysis highlighted increased levels of *Mki67* (coding for Ki67), *Brca1*, *Brca2*, *Rad18*, *Rad51*, *Blm*, *Exo1*, or *Rpa1* (genes involved in the DSB repair mechanism) as well as *Cdc45*, *Bub1*, *Mad2*, and *Rad21* (genes related to checkpoint controls of the cell cycle and to abnormal mitosis) (Supplemental Figure 2C).

Cyclin A2 loss in CECs leads to increased proliferation of CECs and onset of dysplasia. To validate the RNA-Seq results described above at the functional level, we first tested the proliferation status of cyclin A2-deficient CECs by measuring BrdU uptake. For this, mice received an intraperitoneal injection of the nucleoside analog BrdU and were sacrificed 2 hours later to isolate colons. We performed subsequent immunohistochemical analysis by dissecting the different regions of the colon as described above (Supplemental Figure 1A) and by separating the bottom, middle, and top parts of the crypts. As shown in Figure 2A, BrdU⁺ cells were mainly located in the bottom of the crypts in control mice. In contrast, BrdU incorporation was most prominent in the middle part of the cyclin A2-deficient crypts, with an average of more than 4 cells per crypt ($n = 60$, $P < 0.0001$). Moreover, we detected BrdU⁺ cells in the upper crypts of *VilCre Ccna2^{fl/fl}* mice but not in those of control mice. These specific profiles of BrdU incorporation of cyclin A2-deficient CECs were observed equally in the distal, transverse, and proximal regions. To confirm the increased proliferation rate of cyclin A2-deficient CECs, we analyzed Ki67, which is expressed during all active phases of the cell cycle (i.e., G₁, S, G₂, and M) but is absent in resting cells (29). We detected Ki67 expression in the distal region of colons at the bottom of the crypts in colons of control mice, but its expression was localized to the middle and upper parts of the colonic crypts of *Ccna2*-KO animals. We observed a

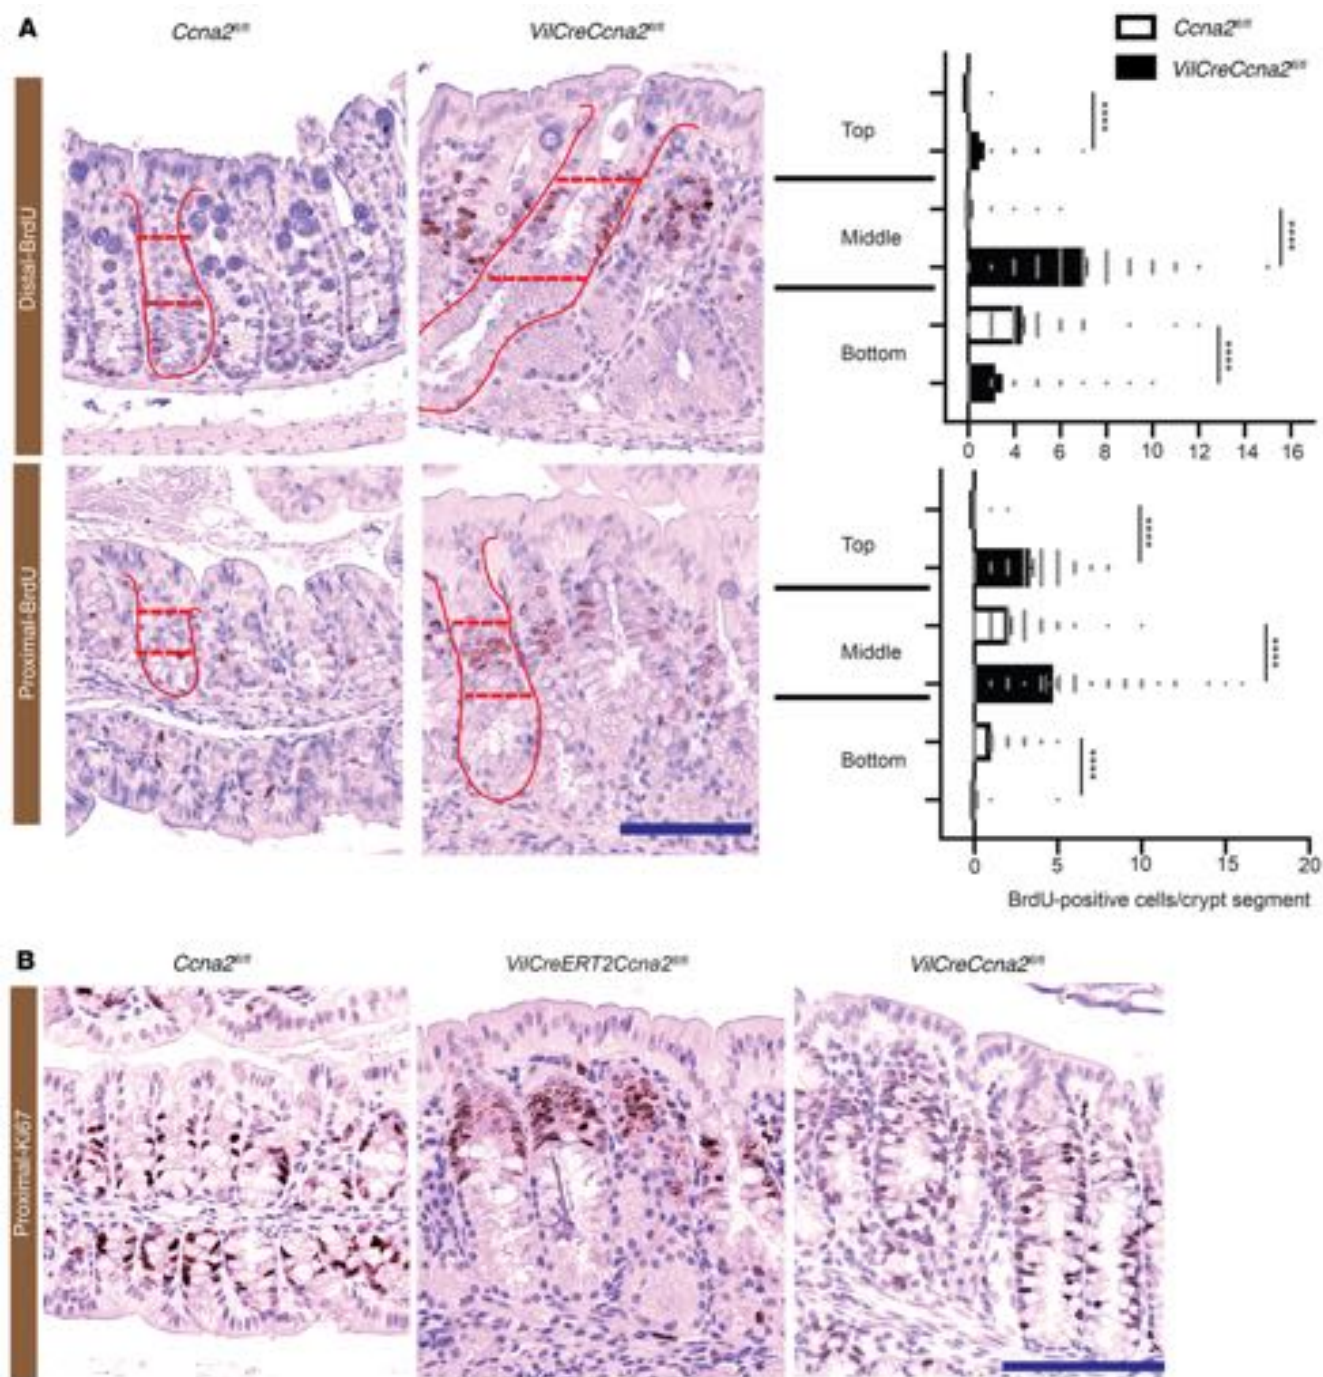

Figure 2. Cyclin A2 depletion in CECs promotes cell proliferation. (A) Analysis of cell proliferation in colonic crypts of control (*Ccna2^{fl/fl}*) and cyclin A2-deficient (*VilCre Ccna2^{fl/fl}*) mice by BrdU incorporation. Shown are representative images of immunostainings for BrdU of the distal and proximal parts of colons taken from *Ccna2^{fl/fl}* and *VilCre Ccna2^{fl/fl}* mice 2 hours after intraperitoneal injection of the nucleoside analog. Plots show quantification of the number of BrdU⁺ cells per crypt segment. Crypts (outlined in red in the images) were subdivided into 3 parts (dotted lines) for the analysis (bottom, middle, and top; $n = 120$ crypts for the distal and $n = 110$ crypts for the proximal parts of colons from 3 different mice). Data represent the mean \pm SEM. **** $P < 0.0001$, by unpaired, 2-tailed Student's t test. (B) Representative images of Ki67 immunostaining in the proximal part of colons from control animals (*Ccna2^{fl/fl}*), induced KO mice 8 days after tamoxifen treatment (*VilCreERT2 Ccna2^{fl/fl}*), and constitutive KO mice (*VilCre Ccna2^{fl/fl}*). Scale bars: 100 μ m.

similar pattern in the proximal region of colons (Figure 2B and Supplemental Figure 3, A and B) from constitutive as well as induced KO mice (Supplemental Figure 3C), therefore confirming the observation made in the BrdU-uptake experiment. Thus, the elevated expression levels of Ki67 observed by immunostaining in

cyclin A2-deficient colons concur with the upregulation of *Mki67* transcripts detected in the RNA-Seq analysis.

We next tested whether expansion of the proliferative compartment in the middle part of cyclin A2-deficient crypts is associated with reprogramming toward a stem cell-like phenotype. For

this, we used CD44v6, which was originally described as a marker for constitutive and reprogrammed cancer stem cells (30) but was later found to also be expressed by cells at the bottom of normal colonic crypts, where colonic epithelial stem cells are localized (31). Indeed, we detected distinct expression of CD44v6 by cells at the base of the normal crypts, but a strong upregulation of CD44v6 levels in the abnormal Ki67⁺ compartment of cyclin A2-deficient crypts (Supplemental Figure 4).

Strikingly, in approximately 80% of the mice analyzed, colons deficient for cyclin A2, either constitutive or induced, revealed low- and high-grade dysplasia that was mostly found in the proximal region (Figure 3, A and B). Constitutive KO mice showed an average occurrence of 4 low-grade dysplasias and nearly 2 high-grade dysplasias per colon. Induced KO mice had a mean of approximately 3 low-grade and high-grade dysplasias per colon, whereas no dysplasia was detectable in the control mice (Figure 3, C and D). Notably, dysplasia was already detectable 8 days after tamoxifen injection in *VilCreERT2 Ccna2^{fl/fl}* mice.

Cyclin A2 depletion in CECs leads to abnormal mitoses and DNA damage. We further explored cell-cycle features and noticed an increased incidence of mitoses within the crypts when analyzing colons of constitutive and induced KO mice (on day 8). Colons with constitutive and induced *Ccna2* deletion showed an average of 13 and 24 mitotic figures per mm², respectively, whereas in control animals, we observed mitotic figures that were on average only 2 per mm² ($n = 5$, $P < 0.01$ for the constitutive as well as induced KO mouse strain) (Figure 4, A and B). In addition, CECs deficient for cyclin A2 harbored nuclear pleomorphisms characterized by increased nuclear size compared with controls (Figure 4A and Supplemental Figure 5). Finally, abnormal mitosis, detected by combined staining for α -tubulin to visualize mitotic spindles, γ -tubulin to label centrosomes, and DAPI to identify chromosomes, was prominent in induced cyclin A2-deficient colons but not in control colons (Supplemental Figure 6, A and B).

Defective mitoses can lead to DNA damage (32), thus, we analyzed colons of tamoxifen-treated *VilCreERT2 Ccna2^{fl/fl}* mice by IHC using a marker for DSBs, i.e., an anti- γ H2AX antibody, and found an average of more than 70 γ H2AX⁺ cells/mm² in cyclin A2-deficient CECs compared with 40 in control CECs (Figure 4C; $n = 4$, $P < 0.05$). Mre11 is part of the NMR complex involved in the resolution of dsDNA (33). We therefore analyzed Mre11 foci formation by confocal microscopy (34) and found that Mre11 foci formation was significantly increased in *VilCre Ccna2^{fl/fl}* nuclei (Figure 4D).

Altogether, the alterations found at the protein level correlated with the RNA-Seq results, underpinning the presence of cell-cycle perturbations, increased DNA damage, and DNA DSB repair pathway activation in cyclin A2-deficient CECs.

Activation of regenerative pathways in cyclin A2-deficient colons. Tissue injury induces inflammation and, in turn, a regenerative response (35). Several pathways have been described that can promote tissue repair in the intestine including YAP/TAZ, NF- κ B, and WNT/ β -catenin signaling (35, 36). We have previously shown that cyclin A2 inactivation in epithelial cells in vitro leads to increased β -catenin stability and activity (18, 19). For this reason, we first tested β -catenin expression in the colons of constitutive KO mice by immunohistochemical analysis, which revealed increased nuclear localization of β -catenin in CECs of cyclin A2-deficient colons (Figure 5A).

In addition, Western blot analysis of nuclear extracts derived from the constitutive KO mice displayed elevated levels of both active β -catenin and the NF- κ B p65 subunit (Figure 5B, left panel). We also detected TAZ expression in crypts as well as surrounding stroma in colons of *VilCre Ccna2^{fl/fl}* mice (Figure 5D, right panel).

To investigate the activation sequence of the different pathways modulated in cyclin A2-deficient CECs at the protein level, we took advantage of the inducible Cre mouse model (*VilCreERT2 Ccna2^{fl/fl}* mice). Two tamoxifen injections on days 0 and 2 were sufficient to abrogate cyclin A2 expression in *VilCreERT2 Ccna2^{fl/fl}* mice (Figure 5B, middle and right panels). We performed Western blot analysis on days 2 and 4 upon *Ccna2* depletion when the colons still showed no alterations such as changes in crypt architecture or immune cell infiltration (Supplemental Figure 7, A and B). We measured the expression levels of active β -catenin and NF- κ B by Western blotting (Figure 5B), as well as expression of γ H2AX and TAZ by IHC (Figure 5, C and D, and Supplemental Figure 7A). In addition, we performed quantification of mitoses on H&E-stained colons from induced KO mice, also on days 2 and 4 (Supplemental Figure 7B, right panel). An increase in mitoses as well as DNA damage, monitored by γ H2AX staining, were already detectable on day 2 and were further increased on day 4 in cyclin A2-deficient CECs (Figure 5C, and Supplemental Figure 7, A and B). This concurs with the elevated number of Mre11 foci, which were detectable by day 2 and progressed with time after cyclin A2 inactivation (Supplemental Figure 7C). In contrast, activation of β -catenin was only detectable on day 4, thus after the induction of DNA damage on day 2, whereas NF- κ B and TAZ levels were unaltered at those time points (Figure 5B, middle and right panels, and Figure 5D). To test whether elevated β -catenin activation (nuclear staining) and/or DNA damage are associated with the abnormal Ki67⁺ compartment in cyclin A2-deficient colons, we performed costainings, which revealed that nuclear active β -catenin and γ H2AX were predominantly present in the lower and upper parts of the crypts, respectively, and that these parts were devoid of Ki67 (Supplemental Figures 8 and 9).

To further explore the alterations in cyclin A2-deficient colonic epithelium, we generated organoids. During the process of extraction from colon, we noticed an increased fragility of the cyclin A2-deficient crypts, yielding a reduced number of crypts when compared with controls, with a mean of 2300 and 9500 crypts per colon, respectively ($n = 7$, $P < 0.001$; Figure 6A). More important, while colon organoids derived from *Ccna2^{fl/fl}* mice were budding on day 4 of culturing, the organoids derived from *VilCre Ccna2^{fl/fl}* mice were mainly forming cysts in the presence of normal organoid media containing WNT3a (i.e., WENR media containing WNT3a, EGF, noggin, R-spondin) (Figure 6B). Cyst formation has been observed on intestinal organoids from APC-mutant mice (37). We therefore cultivated cyclin A2-deficient crypts in the absence of WNT3a (ENR media) and found them to be able to bud under this condition (Figure 6C). The formation of cysts in cyclin A2-deficient organoids appeared therefore be related to an increased activation of β -catenin signaling, thus concurring with the results obtained by Western blotting and immunohistological analysis of colons.

Cyclin A2 deficiency in CECs promotes colon carcinogenesis in mice. To test whether cyclin A2 deficiency modulates colon carcinogenesis, we subjected *VilCre Ccna2^{fl/fl}* and *Ccna2^{fl/fl}* mice to chemically induced colon carcinogenesis, an established mouse

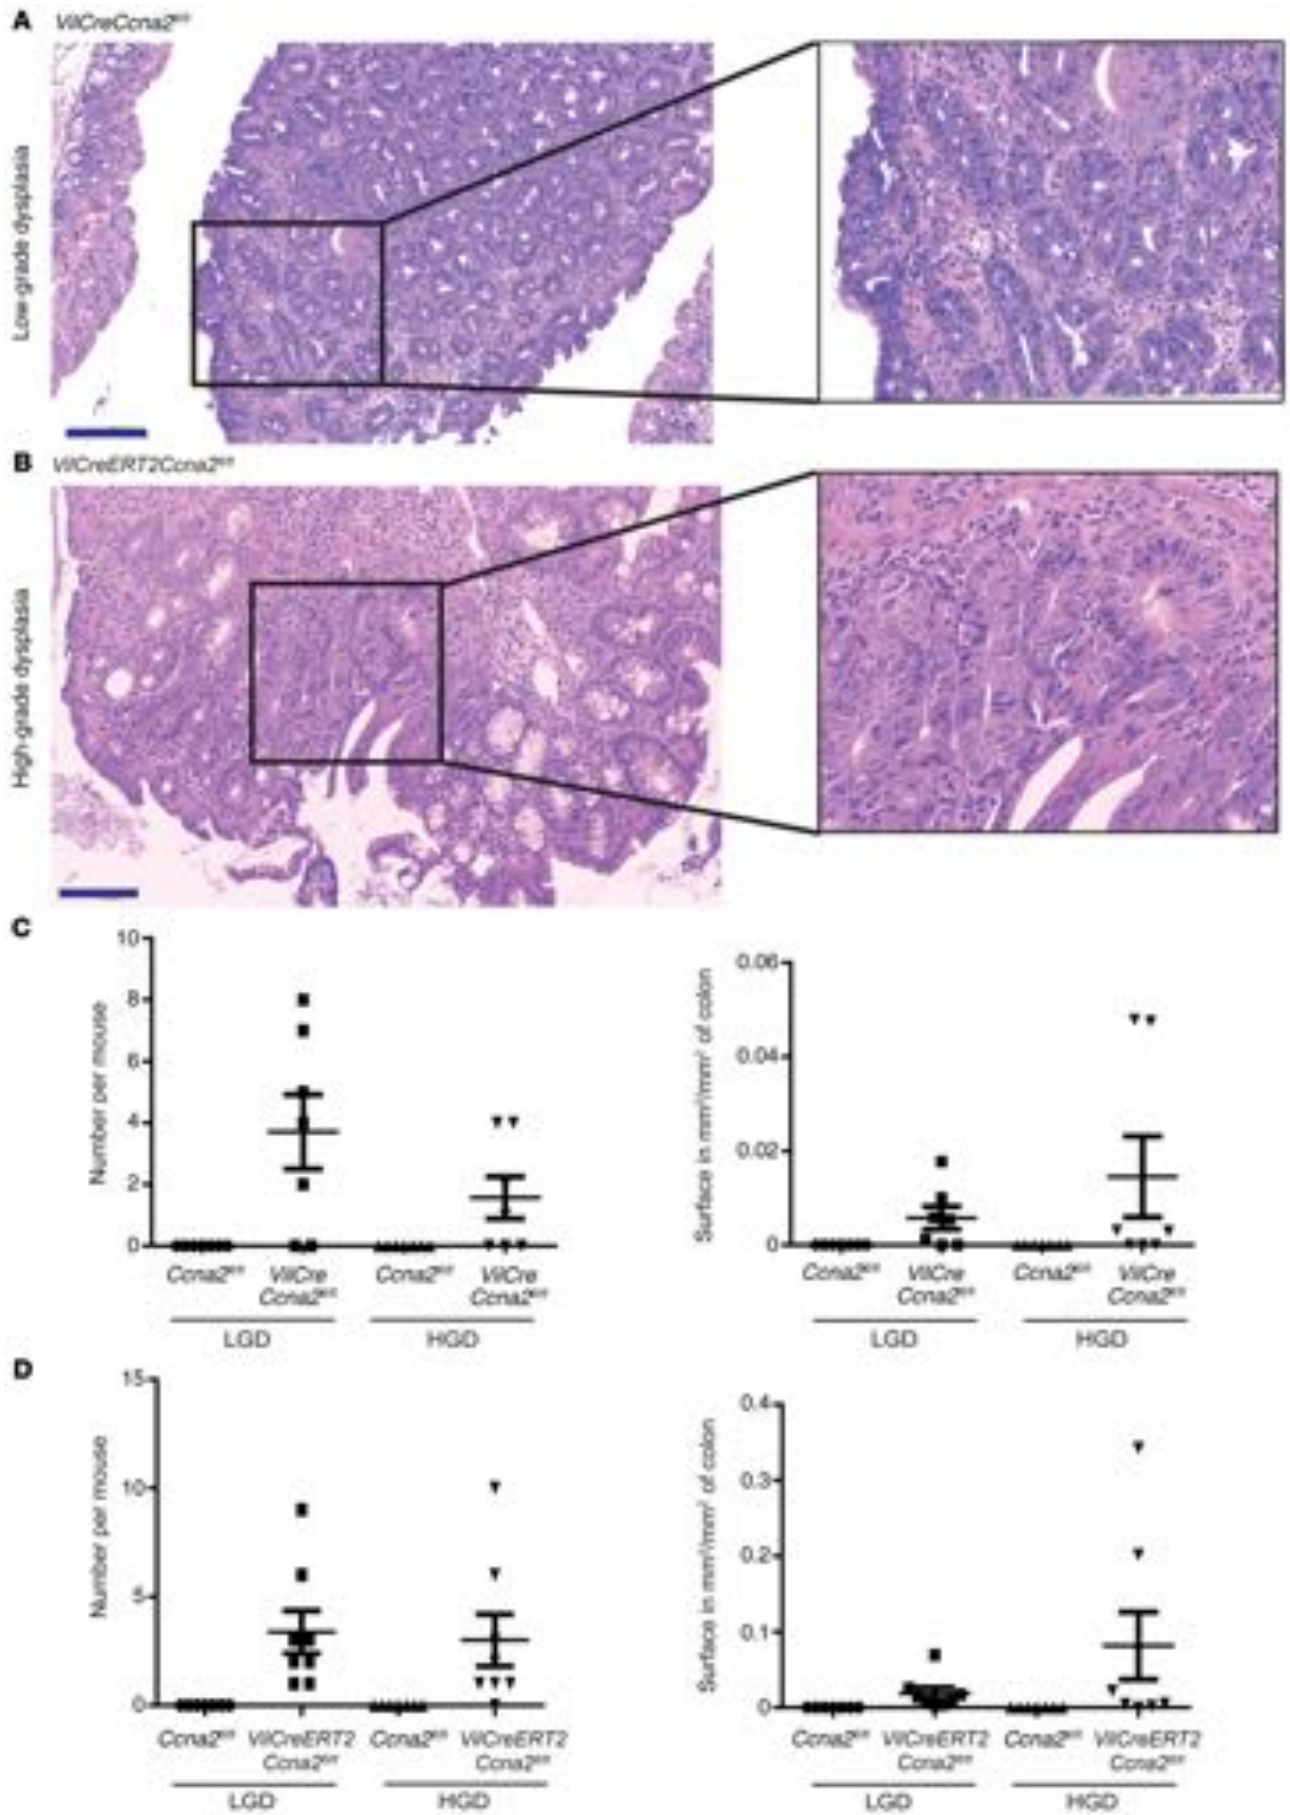

Figure 3. Dysplasia formation in cyclin A2-deficient mice. (A and B) Representative images of H&E staining showing low-grade dysplasia (LGD) and high-grade dysplasia (HGD) in the colons of constitutive (*VilCre Ccna2^{fl/fl}*) (A) and tamoxifen-induced (*VilCreERT2 Ccna2^{fl/fl}*) KO (B) mice. Scale bars: 100 μm . Original magnification, $\times 2$ (enlarged insets). (C and D) Quantification of the number of low- and high-grade dysplasias and dysplasia areas (in mm^2/mm^2 of colon) in constitutive *VilCre Ccna2^{fl/fl}* ($n = 7$) mice and *VilCreERT2 Ccna2^{fl/fl}* induced KO mice 8 days after tamoxifen treatment ($n = 8$) versus control *Ccna2^{fl/fl}* animals ($n = 7$). Data represent the mean \pm SEM. Statistical analysis was performed using an unpaired, 2-tailed Student's *t* test.

model resembling the human pathology (38). This model depends on the intraperitoneal injection of the mutagen azoxymethane (AOM) and the subsequent induction of inflammation by adding dextran sodium sulfate (DSS) in the drinking water, and is therefore named colitis-associated carcinogenesis (CAC). DSS is toxic to mucosal epithelial cells, specifically in the colon, and the destruction of the mucosal barrier leads to chronic inflammation. In the classical protocol, mice receive 3 DSS treatments for 5 days within 60 days, leading to tumor lesions in the distal region of the colon (38). *VilCre Ccna2^{fl/fl}* mice displayed an approximately 2-fold greater weight loss on days 10 through 15 following the first DSS administration compared with control mice (Supplemental Figure 10). We therefore decided not to administer additional doses of DSS to the mice. Mice were sacrificed 60 days after the AOM injection, and colons isolated and embedded in paraffin. The grade of colitis was evaluated as described in Supplemental Table 3 (39) and was 3-fold higher in cyclin A2-deficient mice ($n = 6$, $P \leq 0.05$; Figure 7A). Differences included submucosal alterations as well as transmural disruption by immune cell infiltration, which was undetectable in control mice (Figure 7, A and B). The colon architecture was strongly affected in cyclin A2-deficient mice (Figure 7C), and the incidence of low- and high-grade dysplasia was pronounced in the *VilCre Ccna2^{fl/fl}* mice but was rather rare in the control animals (Figure 7D). Moreover, the surface area of both low- and high-grade dysplasias was significantly higher in the cyclin A2-deficient mice compared with the control animals (Figure 7E). In addition, adenocarcinomas were only detectable in cyclin A2-deleted mice, but not in controls (Figure 7, D and E). Immunohistochemical analysis revealed increased expression levels of activated β -catenin, γH2AX , as well as IL-6 in cyclin A2-deficient colons compared with levels in the control animals (Figure 8).

We next evaluated the impact of cyclin A2 deletion on established tumor lesions. For this, we exposed *VilCreERT2 Ccna2^{fl/fl}* and *Ccna2^{fl/fl}* mice to the classical AOM/DSS protocol described in Figure 9A and subsequently induced cyclin A2 deletion by 2 consecutive tamoxifen injections. Approximately 40 days later, the mice were sacrificed for immunohistological analysis that revealed an increased number of adenocarcinomas in cyclin A2-deficient colons (Figure 9B), which were characterized by elevated expression levels of the stemness marker CD44v6 (30) (Figure 9, C and D). Strikingly, invasive adenocarcinomas were detectable only in the proximal part of the colons of cyclin A2-deficient mice and absent in those of controls. Notably, the invasive adenocarcinoma displayed abundant CD44v6 expression, whereas the desmoplastic stroma of the invading tumors showed prominent TGF- β expression (Figure 9C).

Altogether, these observations show that cyclin A2 deficiency in CECs promoted chemically induced colon carcinogenesis in mice.

Cyclin A2 expression in patients with CRC has prognostic value. Our finding that cyclin A2 deficiency in mice promoted spontaneous development of dysplasia in the colon as well as induced colon carcinogenesis prompted us to perform a meta-analysis of *CCNA2* expression on available public data sets (Supplemental Table 4). The characteristics of the 2239 patients with CRC profiled are summarized in Supplemental Table 5. Briefly, the median age of the patients was 68 years (range, 19–97 years), and the sex ratio was balanced, with 47% of female patients and 53% male patients. The most frequent location was the right colon, followed by the left colon and sigmoid. The pathological stage included more stage 3–4 than stage 1–2 cancers. The pathological grade was mostly 2, and the mismatch repair (MMR) status was microsatellite stable (MSS) in most cases. The CMS classification identified 20% of samples as CMS1 (microsatellite instability [MSI] immune), 32% as CMS2 (canonical), 17% as CMS3 (metabolic), and 31% as CMS4 (mesenchymal).

CCNA2 expression was heterogeneous across the 2239 primary CRC (pCRC) tumors analyzed (Figure 10A). Compared with normal colon (NC) tissues, *CCNA2* transcript levels were upregulated in most of the primary tumors. In contrast, expression levels in CRC metastases (ANOVA, $P = 4.16 \times 10^{-54}$) were significantly lower compared with levels in primary tumors (Figure 10A). In addition, we found that *CCNA2* transcript levels were lower in the stages 3–4 versus stages 1–2 (Figure 10B). In parallel, we used 2 different cyclin A2 antibodies to evaluate cyclin A2 protein expression by IHC on a tissue microarray (TMA) of CRC biopsies taken from 65 patients from stage 1 to stage 4 (described in Supplemental Table 6) (Figure 10C, and Supplemental Figure 12A, and see Methods). We quantified cyclin A2 expression as the number of epithelium-positive cells per mm^2 of tumor area. Immunohistochemical analysis confirmed the transcriptome data by revealing cyclin A2 protein levels to be lower in stages 3 and 4 than in early stages (Figure 10C, and Supplemental Figure 12A). In addition, we observed lower cyclin A2 levels in stage 2 MSS compared with levels detected in MSI tumors (Figure 10C, and Supplemental Figure 12, A and B). We next evaluated *CCNA2* levels according to the CMS classification (8) and observed that *CCNA2* expression was highest in the CMS1 class, lowest in the CMS4 class, and intermediate in the CMS2 and CMS3 classes (Figure 10E).

We next measured *CCNA2* expression as a discrete value after comparison with the median expression of the 95 NC samples; upregulation, hereafter designated as *CCNA2^{hi}* ($n = 1139$), was defined as a CRC/NC ratio of 2 or higher, and no upregulation, designated as *CCNA2^{non-hi}* ($n = 1100$), was defined as a CRC/NC ratio of less than 2. We searched for correlations between the *CCNA2^{hi}* or *CCNA2^{non-hi}* classification and the clinicopathological and molecular variables of the 2239 pCRC samples (Supplemental Table 5) and found no correlation between *CCNA2* mRNA levels and patients' age or sex. By contrast, when compared with the *CCNA2^{non-hi}* class, the *CCNA2^{hi}* class was associated with more frequent right and left tumor locations ($P = 2.04 \times 10^{-2}$, Fisher's exact test), pathological stages 1 and 2 ($P = 3.19 \times 10^{-8}$; Supplemental Table 5 and Figure 10B), pathological grade 3 ($P = 5.99 \times 10^{-03}$), as well as MSI status ($P = 1.48 \times 10^{-5}$) and CMS1 molecular subtype ($P = 1.00 \times 10^{-6}$).

Relapse-free-survival (RFS) data were available for 1882 of 2239 operated pCRC samples. The median follow-up was 42

Figure 4. Elevated mitoses and DNA damage following cyclin A2 deletion in the colonic epithelium. (A) Representative H&E staining showing an increased number of mitoses (red arrowheads) in the proximal region of colon from a cyclin A2-deficient mouse compared with colon from a control animal. Scale bar: 100 μ m. Original magnification, $\times 2$ (enlarged inset). (B) Quantification of mitotic events in constitutive mice (left: $n = 5$), induced KO mice 8 days after cyclin A2 inactivation (right: $n = 5$), and control animals ($n = 5$). Data represent the mean \pm SEM. $^{**}P < 0.01$, by unpaired, 2-tailed Student's t test. (C) Immunohistochemical analysis of γ H2AX expression in colon sections of control *Ccna2^{fl/fl}* mice ($n = 5$) and *VilCreERT2 Ccna2^{fl/fl}* tamoxifen-induced KO mice ($n = 4$) on day 8 following cyclin A2 inactivation. Representative γ H2AX immunostaining images and quantification of the number of γ H2AX⁺ cells per mm² of epithelium from the proximal part of the colon are shown. Data represent the mean \pm SEM. $^{*}P < 0.05$, by unpaired, 2-tailed Student's t test. Scale bar: 100 μ m. Original magnification, $\times 2$ (enlarged inset). (D) Confocal analysis of nuclear foci formation of Mre11 in crypts from the proximal part of colons from control *Ccna2^{fl/fl}* and *VilCre Ccna2^{fl/fl}* mice. Representative images are shown. Nuclei are stained with DAPI (blue) and Mre11 (red). Scale bar: 10 μ m. Plot shows quantification of Mre11 fluorescence intensity per nuclear surface ($n = 83$ different nuclear areas for control mice and $n = 65$ for cyclin A2-deficient mice). Data represent the mean \pm SEM. $^{*}P < 0.05$, by unpaired, 2-tailed Student's t test.

months (range, 1–212); 496 patients (26%) had an event, and the 5-year RFS was 70% (95% CI: 68–73; Supplemental Figure 11A). Interestingly, the clinical outcome was different between the two *CCNA2*-based classes, with 281 events (31%) in the *CCNA2^{non-hi}* class ($n = 894$) versus 215 events (22%) in the *CCNA2^{hi}* class ($n = 988$; $P = 2.32 \times 10^{-6}$, Fisher's exact test; Supplemental Table 5). The 5-year RFS was lower (65%) for *CCNA2^{non-hi}* patients (95% CI: 61–69) versus 75% (95% CI: 72–79) for the *CCNA2^{hi}* patients, respectively ($P = 8.86 \times 10^{-6}$; Figure 10D). In univariate analysis for RFS (Supplemental Table 7), the HR for the event was 0.67 (95% CI: 0.56–0.80) in the *CCNA2^{hi}* class when compared with the HR for the *CCNA2^{non-hi}* class ($P = 1.01 \times 10^{-5}$, Wald's test). Other variables associated with RFS included the tumor location ($P = 1.35 \times 10^{-6}$), the pathological stage ($P = 2.78 \times 10^{-15}$), and MMR status ($P = 2.97 \times 10^{-4}$) (with the *CCNA2^{non-hi}* class being predominantly associated with MSS status, in agreement with the results obtained with the TMA), unlike patients' age, sex, and pathological grade. In multivariate analysis (Supplemental Table 7), the *CCNA2*-based classification remained associated with RFS ($P = 2.99 \times 10^{-3}$, Wald's test), as well as tumor location (right and sigmoid colon), pathological stage, and MMR status. Of note, this association remained significant ($P = 4.13 \times 10^{-4}$) in multivariate analysis incorporating the CMS molecular classification (Supplemental Table 7). As shown in Figure 10F, the RFS was affected for the 8 classes defined by both *CCNA2* expression levels and CMS ($P = 1.82 \times 10^{-6}$, log-rank test): *CCNA2* expression levels correlated with the clinical outcome for 3 CMSs, with a significantly reduced RFS for patients with *CCNA2^{non-hi}* tumors compared with patients in the *CCNA2^{hi}* class for CMS1 (59% versus 73, $P = 1.64 \times 10^{-2}$), CMS3 (62% versus 79%, $P = 0.05$), and CMS4 subtypes (60% vs. 74%, $P = 2.08 \times 10^{-2}$) (Figure 10E).

To further explore the biological alterations associated with *CCNA2* expression, we compared the whole-genome expression profiles of *CCNA2^{non-hi}* ($n = 222$) and *CCNA2^{hi}* ($n = 237$) The Cancer Genome Atlas (TCGA) samples (learning set) (Supplemental Figure 11, B and C). We identified 92 genes that were differentially expressed, including 20 genes overexpressed and 72 genes

underexpressed in the *CCNA2^{hi}* class (Supplemental Figure 11C, and Supplemental Table 8). We used the gene expression signature (GES) of 92 genes based on the metagene analysis to classify samples. As expected, this GES allowed efficient classification of the 459 learning set samples ($P = 1.08 \times 10^{-52}$, Student's t test). More important, we validated its robustness in a completely independent validation set that included the 1780 remaining samples ($P = 9.22 \times 10^{-180}$, Student's t test; Supplemental Figure 11B). A detailed analysis of the 92 genes revealed that the 20 most significantly upregulated genes are involved in cell proliferation and DNA repair (mitotic cell-cycle regulation, genomic instability, and replicative immortality pathways) (Supplemental Table 8).

Discussion

Cyclins are well-established drivers of the cell cycle through activation of a specific family of kinases, the cyclin-dependent kinases (CDKs). Gene amplification as well as overexpression of cyclins have been frequently detected in cancer tissues, and cyclins have been proposed as biomarkers or therapeutic targets (40). For example, inhibition of cyclin A2 complexes has been shown to impair the proliferation of some tumor cell lines (41).

Here, we report that cyclin A2 deficiency in CECs led to epithelial changes in the mucosa, induced inflammation, and increased cell proliferation and dysplasia in the colon, rendering the mice more susceptible to chemically induced colon carcinogenesis. A higher incidence of mitoses as well as DNA DSBs were detectable as early as 2 days after cyclin A2 inactivation and appeared, therefore, to be the initial events, as elevated activation of β -catenin was only detectable on day 4, upon cyclin A2 deletion, followed later on by activation of NF- κ B and TAZ. Therefore, cyclin A2 deficiency in CECs led to different molecular alterations, with DNA damage and abundant mitoses as the initiating events, followed by activation of β -catenin and the regenerative and inflammatory pathways involving TAZ and NF- κ B. Our immunohistochemical analysis suggested a spatial separation of DNA damage and β -catenin activation in cyclin A2-deficient colons, with nuclear staining of active β -catenin being more frequent in the lower part of the colonic crypts, i.e., below the proliferative Ki67⁺ compartment, whereas γ H2AX staining was localized in the upper crypt region (Supplemental Figures 8 and 9). Furthermore, we found that the expanded proliferative Ki67⁺ compartment in cyclin A2-deficient colons gained a stem-like phenotype as revealed by immunostaining for CD44v6, an established colon cancer stem cell marker and driver of metastasis (30).

It is well established that the WNT/ β -catenin pathway triggers regeneration in certain tissues by controlling the stem cell compartment, and it has also been shown to cooperate with the YAP/TAZ pathway during colonic tissue repair and regeneration (36, 42). Furthermore, elevated NF- κ B activation in combination with signals from the inflammatory microenvironment has been shown to increase WNT activation and lead to dedifferentiation of non-stem cells in tumor-initiating and cancer stem cell entities (43–45). This could explain the acquisition of the CD44v6 stem-like phenotype of the proliferative cyclin A2-deficient cells localized in the middle parts of the crypts. On the other hand, 1 study showed that cyclin A2 is involved in stabilizing the axin/GSK3 destruction complex, thereby promoting β -catenin degradation (46). This finding could explain the nuclear accumulation of β -catenin detected in

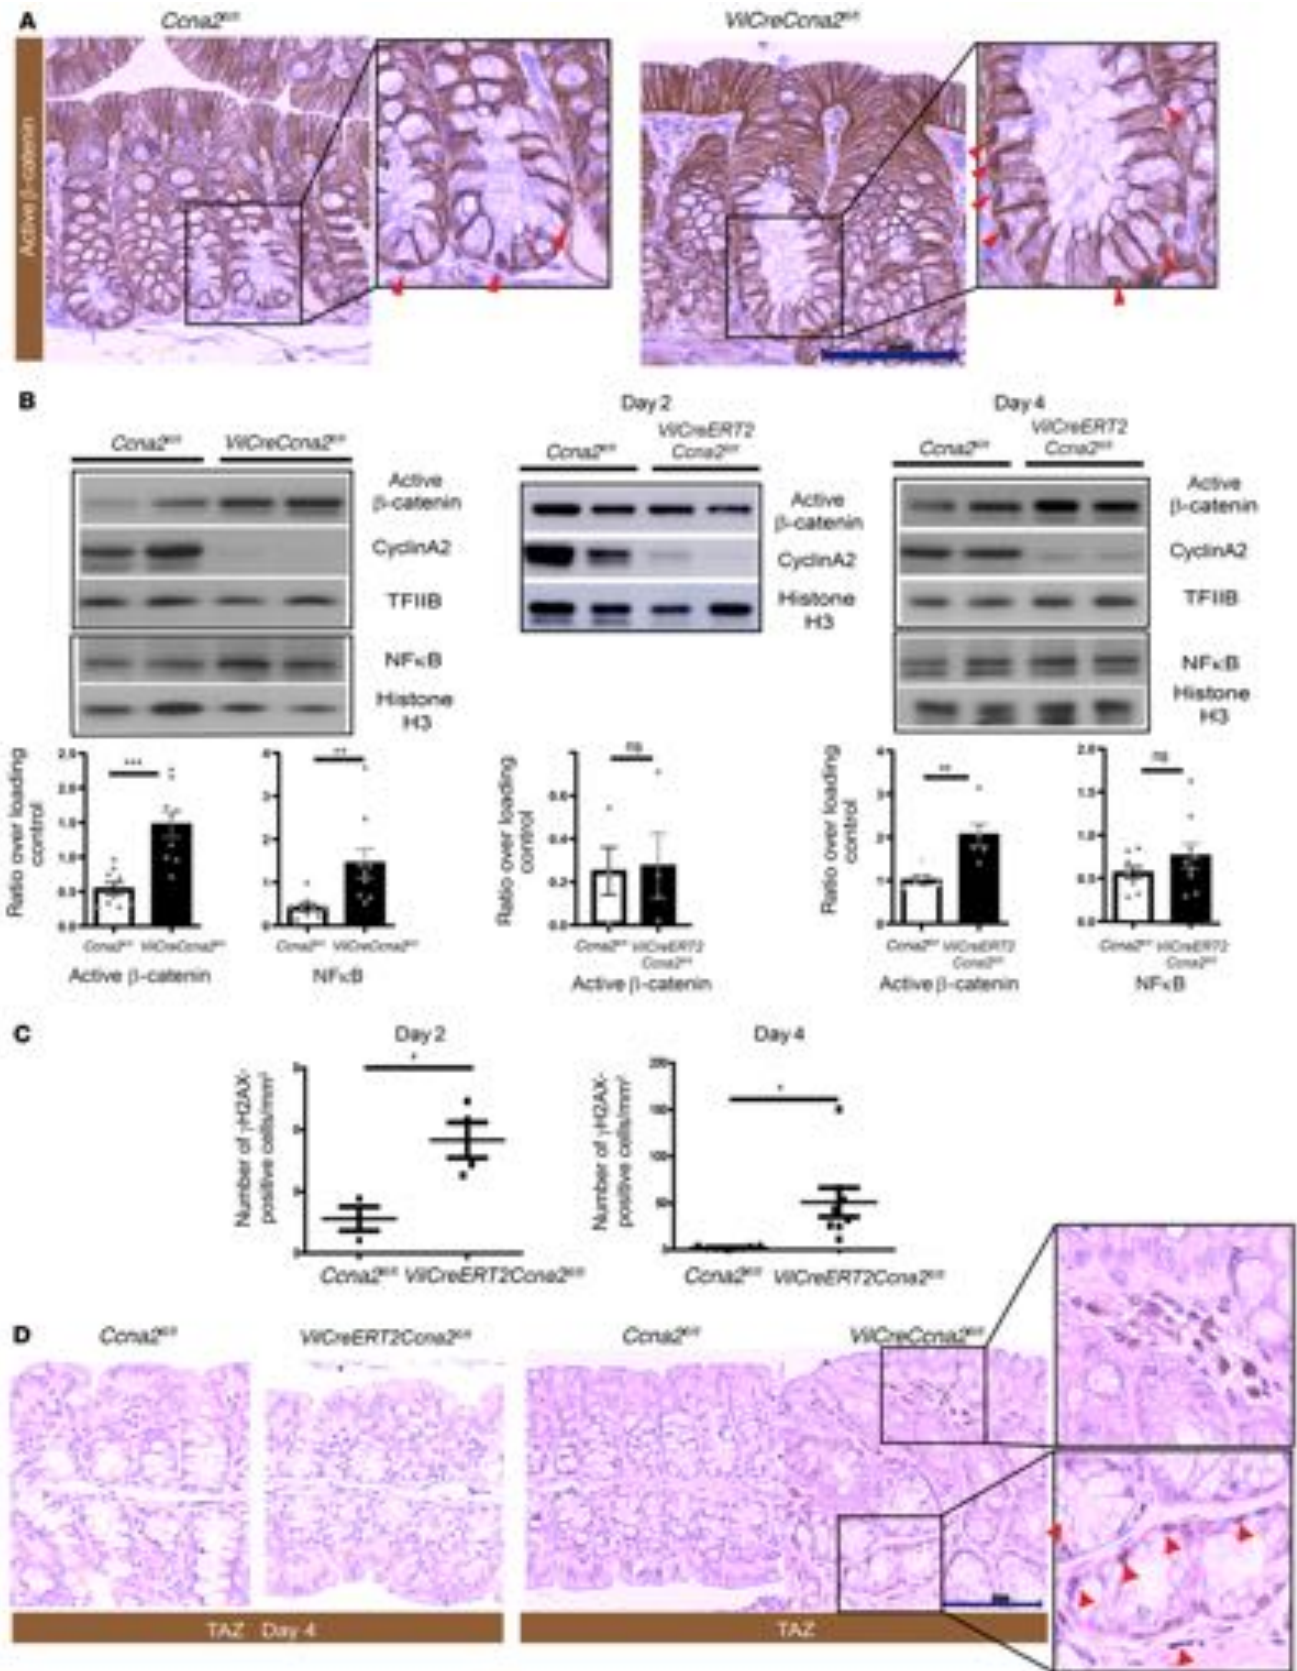

Figure 5. Cyclin A2 deficiency triggers regenerative pathways. (A) Representative immunostainings for active β -catenin in control (*Ccna2^{fl/fl}*) and constitutive KO (*VilCre Ccna2^{fl/fl}*) mice. Arrowheads indicate nuclear localization of active β -catenin. Scale bar: 100 μ m. Original magnification, $\times 2$ (enlarged insets). (B) Western blot analysis of active β -catenin and NF- κ B in nuclear extracts of CECs derived from constitutive cyclin A2-deficient mice ($n = 9$), their littermate controls (left panel), and tamoxifen-induced KO mice (*VilCreERT2 Ccna2^{fl/fl}*) following deletion of cyclin A2 on day 2 ($n = 4$, middle panel) and day 4 ($n = 6$ for β -catenin and $n = 9$ for NF- κ B, right panel). Lower panels show quantification of active β -catenin and NF- κ B after normalization with loading controls (TFIIB or histone H3). (C) Colons of cyclin A2-deficient mice displayed DNA damage. Plots show quantification of γ H2AX staining in colons of control ($n = 3$) and *VilCreERT2 Ccna2^{fl/fl}* ($n = 4$) mice on days 2 and 4 ($n = 8$) following tamoxifen-induced *Ccna2* depletion. (D) Representative immunostainings of TAZ expression (indicated by arrowheads) in constitutive cyclin A2-deficient colons and induced KO mice on day 4 following *Ccna2* deletion (left panel). Scale bar: 100 μ m. Original magnification, $\times 2$ (enlarged insets). Data represent the mean \pm SEM. * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$, by unpaired, 2-tailed Student's t test.

cyclin A2-deficient colons, as well. In line with this is our previous description that cyclin A2 depletion in murine mammary epithelial cells promotes β -catenin activity (18, 19).

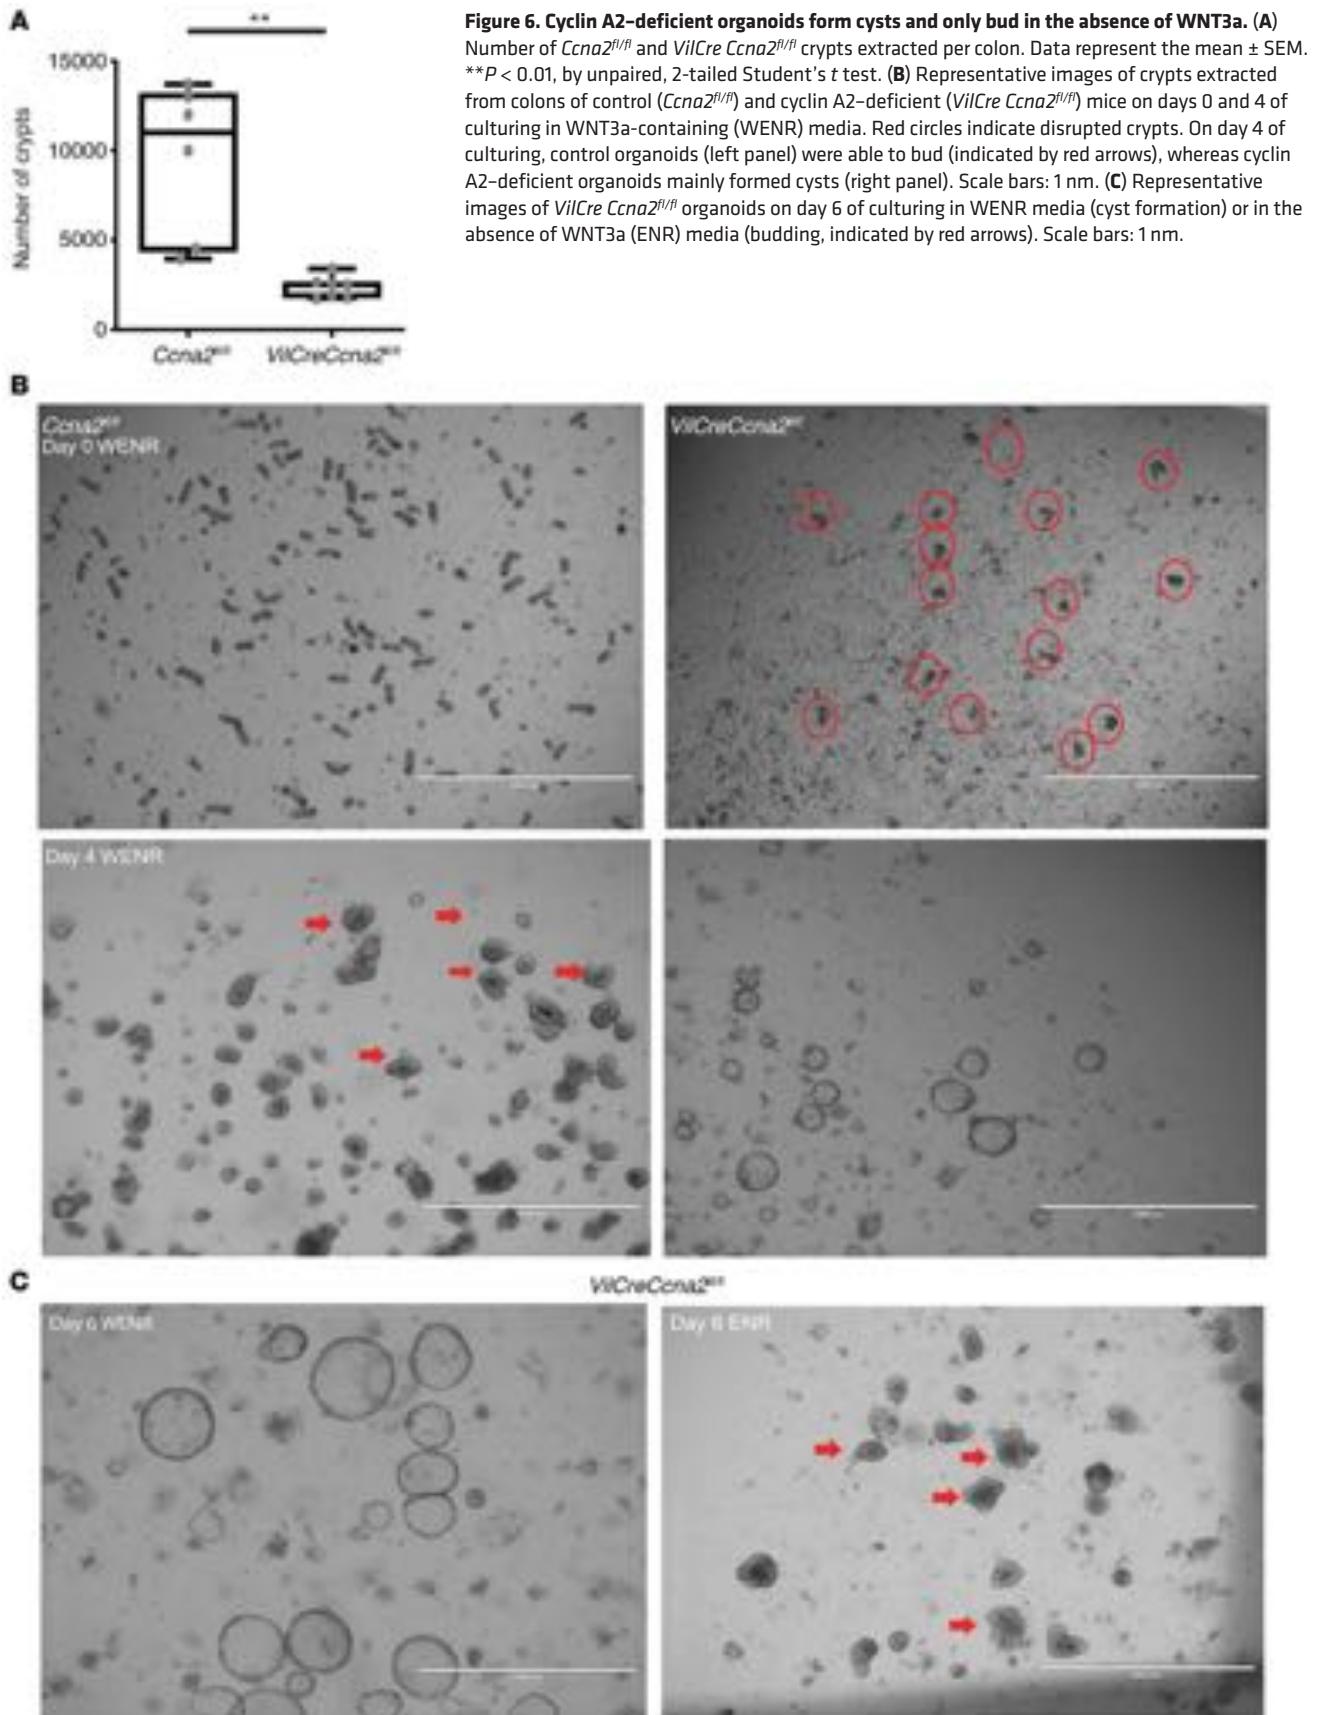

A previous study established a role of cyclin A2 in DNA DSB repair by generating mutant mice bearing cyclin A2-KO and hypomorphic alleles resulting in lower cyclin A2 expression (21). These mice fail to upregulate the meiotic recombination 11 (*Mre11*) nuclease that causes impaired resolution of stalled replication forks, reduced repair of DNA DSBs, aberrant chromosome segregation, and increased spontaneous and chemically induced tumor development (21). The same study reported that cyclin A2 binds to *Mre11* mRNA, thereby promoting its translation. We detected increased *Mre11* foci formation in cyclin A2-deficient CECs, suggesting that the increased DNA damage detected in the colons of cyclin A2-deficient mice resulted rather from a defective regulation of DNA replication and/or chromosome segregation. Indeed, phosphorylation of CDC6 by cyclin A/CDK2 has been shown to prevent re-replication during the S phase and G₂ (47). Moreover, cyclin A2/CDK activity has been demonstrated to be essential for centrosome duplication and proper sister chromatid segregation (48). Of note, the mitoses detected in *VilCre Ccna2^{fl/fl}* mice were mostly located in the middle part of the colonic crypts, whereas γ H2AX⁺ cells were predominantly identified in the upper part. This is in accordance with the fact that the generation of DSBs following abnormal mitosis takes place once a cell exits the mitotic process, entering the next cell cycle (49) thus during its migration toward the top part of the crypts. Notably, high expression levels of γ H2AX have been shown to predict a poor prognosis for patients with CRC (50), and a more recent report described a role for cyclin A2 in preventing chromosomal defects (chromosomal instability [CIN]) in colon cancer cells (51).

It is well established that there is a crosstalk between DNA damage and inflammation and that either event can initiate the other one (52). Colons of cyclin A2-deficient mice displayed different signs of inflammation with infiltration of macrophages as well as production of IL-6 and TGF- β , which correlated with increased activation of NF- κ B in CECs. Recent findings suggest a direct relationship between chromosome mis-segregation, DNA damage, and the induction of a proinflammatory environment (52). In fact,

DNA DSBs were shown to promote the production of IL-6 and the TGF- β family ligands (53, 54). Altogether, this suggests that the inflammatory response in cyclin A2-deficient mice is mounted as well in response to active genomic instability.

A large proportion of macrophages expressed YM1, indicating a predominant M2 polarization (Supplemental Figure 1C). Notably, M2-like macrophages have been described to promote tissue repair and remodeling and were attributed a protumoral role that could contribute to the phenotype of the cyclin A2-deficient mice (55). In addition, rectal prolapse was detectable in *VilCre Ccna2^{fl/fl}* mice, a phenomenon that was previously described in a mouse model that develops colitis spontaneously (28). Increased expression and activation of NF- κ B has been observed in IBD and in patients with CRC, especially in mucosal macrophages and epithelial cells. This is accompanied by the production of cytokines including IL-6 and TGF- β , which have been proposed as therapeutic targets for the treatment of IBD (26, 56). Finally, YAP/TAZ overexpression has been shown to promote tumor formation (57) and to correlate with poor prognosis in CRC (58). We therefore conclude that DNA damage, combined with uncontrolled activation of several regenerative pathways, promotes the development of dysplasia in cyclin A2-deficient mice.

Most studies evaluating the prognostic value of cyclin A2 in CRC concluded that cyclin A2 overexpression is an indicator of poor prognosis (59–61), while 1 report described a higher survival rate for patients with tumors expressing high levels of cyclin A2 (62). To clarify the prognostic value of cyclin A2 in CRC, we performed a meta-analysis of 11 publicly available transcriptome data sets comprising 2239 primary tumor samples. This analysis revealed elevated *CCNA2* transcript levels in primary tumors compared with levels in normal tissues as well as metastases, concurring with our previous analysis of biopsies using immunohistochemical and Western blot analysis (17). *CCNA2* transcript expression was higher in tumors of patients with stage 1 or 2 CRC compared with expression levels in patients with stage 3 or 4 disease. Importantly, this concurred with cyclin A2 protein expression analysis by IHC on our TMA. Here, we show that *CCNA2* expression differed among CMS subtypes, with the highest expression levels in the CMS1 subtype and the lowest in the CMS4 subtype. We stratified the transcriptome samples from high and non-high expressors by setting a cutoff of 2 or higher for the *CCNA2* transcript expression ratio of CRC versus normal tissue and found higher RFS rates in the *CCNA2^{hi}* class. Importantly, this favorable prognostic value of high *CCNA2* expression persisted in multivariate analysis incorporating the classical prognostic factors or the CMS subtypes, suggesting an independent prognostic value. Whole-transcriptome supervised analysis of the two *CCNA2* classes revealed that the 20 most significant modulated genes upregulated in the *CCNA2^{hi}* versus the *CCNA2^{non-hi}* classes were all involved in cell proliferation and DNA repair. Although the expression data for multicellular tumor tissues cannot be directly correlated with the data obtained for cell type-specific KO mice, it is remarkable that *CCNA2^{hi}* CRC tumors and cyclin A2 deficiency in murine CECs triggered similar mechanisms such as DNA damage. We also compared the GES of the RNA-Seq analysis from murine colons (*Ccna2^{fl/fl}* versus *VilCre Ccna2^{fl/fl}* mice) with the gene list used to establish the different CMS subtypes and found an overlap of 39 genes, among which 25 (>64%) belonged to the CMS4 subtype (Supplemental Figure 13). Most of these genes

are known targets of TGF- β . This enrichment was significant (Fisher's exact test, $P = 5.10^{-8}$). The CMS4 subtype, considered the "mesenchymal" class, is indeed defined by prominent TGF- β activation, stromal invasion, and angiogenesis and is characterized by a dismal survival outcome. Notably, the invasive adenocarcinoma we detected upon cyclin A2 deletion in the CAC-treated mice displayed CMS4 features, such as stemness and TGF- β expression. We conclude that the expression pattern of cyclin A2 in CRC tissues mirrors distinct roles during colon carcinogenesis, such as driving cell proliferation in early stages, when highly expressed, but promoting aggressiveness in later stages, when expression levels are lower.

Taken together, our results establish that cyclin A2 deficiency in murine CECs induced DNA damage, inflammation, and activation of different regenerative pathways triggering dysplasia. This rendered the mice more susceptible to chemically induced colon carcinogenesis by elevated tumor initiation as well as aggressiveness. Furthermore, cyclin A2 deletion in established tumors appeared to increase their aggressiveness. Our observations in mice were complemented by a meta-analysis of 2239 pCRC tumors, which showed that high *CCNA2* expression is associated with a better prognosis in patients with CRC. Moreover, we describe here for the first time to our knowledge that *CCNA2* expression differs between CMS subtypes. Importantly, classification of the patient cohort into the different CMSs identified *CCNA2*^{non-hi} expression as a poor prognostic factor within CMS1, CMS3, and CMS4, but not CMS2. In conclusion, *CCNA2* expression was strongly correlated with several clinicopathological factors of CRC and may represent a favorable prognostic marker in patients with CRC.

Methods

Generation of cyclin A2 conditional-KO mice in the intestinal epithelium. To generate cyclin A2 intestinal epithelium-specific KO mice, *Ccna2*^{fl/fl} mice, provided by P. Sicinski (Dana Farber Institute, Boston, Massachusetts, USA) (23), were crossed with transgenic mice carrying either a constitutively active Cre recombinase (*vil-Cre*) (provided by Sylvie Robine, Curie Institute, Paris, France) (24), expressed during embryonic development (day 9) throughout adulthood in intestinal epithelial cells, or a tamoxifen-inducible Cre under the same promoter (*vil-Cre-ER^{T2}*) (provided by Robine, Curie Institute, Paris, France) (24), induced in adult mice by 2 intraperitoneal injections of tamoxifen (MilliporeSigma, 150 mg/kg). Mice were maintained on a C57BL6 background. Genotyping was performed using the primers listed in Supplemental Table 9.

Immunohistochemical and immunofluorescence analyses of paraffin-embedded tissue sections. Colons were rolled up lengthwise and embedded in paraffin after fixation in 10% formalin for 24 hours. Tissue slides were deparaffinized and rehydrated in xylene (2 \times 5 min), 100% ethanol (5 min), 96% ethanol (3 min), 70% ethanol (3 min), and dH₂O (5 min). Tissue slides were incubated in 10 mM sodium citrate, pH 6.0, for 20 minutes at 100°C or in 10 mM Tris, 1 mM EDTA, pH 9.0, for antigen retrieval, depending on the antibody. Following 2 washes in PBS-0.2% Tween 20, tissue slides were incubated in PBS with 3% hydrogen (H1009, MilliporeSigma) for 5 minutes at room temperature, blocked in 2.5% blocking serum, 5% BSA, and 5% nonfat milk for 30 minutes at room temperature, and then incubated with a primary antibody for 1 hour at 4°C. The corresponding secondary antibody reagents (ImmPRESS Kit, Vector Laboratories) were used for detection. The primary antibodies used are summarized in Supplemental Table 10.

For H&E staining, tissue slides were incubated in xylene (3 \times 3 min), 100% ethanol (3 \times 3 min), 95% ethanol (3 min), and 80% ethanol (3 min) and then for 5 minutes in deionized water. Slides were then incubated in hematoxylin (Vector Laboratories) for 3 minutes, extensively rinsed in tap water, and dipped in acid ethanol (0.03N HCl, 70% ethanol). After rinsing in water, the slides were transferred into deionized water for 2 minutes and then stained in eosin for 30 seconds (Vector Laboratories), followed by 3 incubations of 5 minutes each in 95% ethanol. After incubations in xylene, the coverslips were mounted using Permount Mounting Medium (Thermo Fisher Scientific). For TMA analysis, the rabbit anti-cyclin A2 antibody (ab181591, Abcam), validated on *Ccna2*-deficient mouse tissues, as well as the rabbit anti-cyclin A2 antibody (NCL-CYCLINA) were used (Supplemental Table 10). Slides were scanned using the Nanozoomer scanner (Hamamatsu Photonics) and analyzed in NDP Viewer with gamma settings modified to accommodate for interslide variability of the HE staining.

For immunofluorescence analysis, the tissue slides were deparaffinized and rehydrated as described above and incubated in 1 mM EDTA antigen retrieval buffer (pH 9.0) for α - and γ -tubulin, or in 10 mM citrate (pH 6) for anti-Mre11 staining. Blocking was performed for 30 minutes in 2.5% blocking serum, 5% BSA, and 5% nonfat milk at room temperature, and tissue slides were then incubated with primary antibodies (see Supplemental Table 10) for 1 hour at 4°C. Depending on the primary antibodies, slides were incubated with goat anti-mouse, -rat, or -rabbit secondary antibodies conjugated to either Alexa Fluor 488 or Alexa Fluor 555 (Thermo Fisher Scientific) in addition to DAPI (0.1 μ g/mL) for 1 hour at room temperature. Mre11 staining images were acquired on the Leica Confocal SP5-SMD, and images were analyzed using Imaris software (Oxford Instruments). For costaining (i.e., α -/ γ -tubulin, Ki67/active β -catenin, Ki67/H2AX, and Ki67/CD44v6), image acquisition in the transverse and proximal colon was performed using Metamorph software (Molecular Devices) on the Upright Zeiss Axioimager Z2 (Zeiss), and images were analyzed using ImageJ software.

BrdU incorporation assay. Mice were intraperitoneally injected with 100 μ g/g BrdU (B9285, MilliporeSigma) diluted in PBS. Colon specimens were dissected 2 hours after injection, flushed with cold PBS, and embedded in paraffin after fixation in 10% formalin for 24 hours. Incorporation of BrdU was detected using an anti-BrdU antibody (Supplemental Table 10) after deparaffinization of the tissues, antigen retrieval in citrate buffer, and DNA denaturation using 2N HCl for 1 hour at 37°C followed by an incubation in 0.1 M borax buffer, pH 9. Revelation was performed using the VECTASTAIN Avidin-Biotin Kit (Vector Laboratories).

Isolation of CECs. Colons were removed from mice, flushed with cold PBS, cut longitudinally, and treated with 10 mL CEC buffer (PBS, 1% BSA, 1 mM EDTA, 1 mM DTT, 5.6 mM glucose) at 37°C for 45 minutes under continuous shaking to release CECs. Cell purity was validated by FACS using the cell-surface markers EpCAM-APC and CD45-PE and CD90.2-FITC (see Supplemental Table 10) to identify epithelial and immune cells, respectively.

Isolation of CEC cytoplasmic and nuclear fractions. Cells were treated with ice-cold hypotonic buffer (10 mM HEPES, pH 7.9, 10 mM KCl, 0.1 mM EDTA, 0.1 mM EGTA, 0.5 mM PMSF, 1 mM DTT) and cOmplete Inhibitor Tabs (MilliporeSigma) for 15 minutes, and then treated with 10% NP40 and vortexed. The nuclei were pelleted by centrifugation (16.1 rcf, 15 s) while the supernatant was kept as the cytoplasmic fraction. Nuclei were lysed in 20 mM HEPES, pH 7.9, 0.4 mM NaCl, 1 mM EDTA, 1 mM EGTA, 0.5 mM PMSF, 1 mM DTT, and cComplete

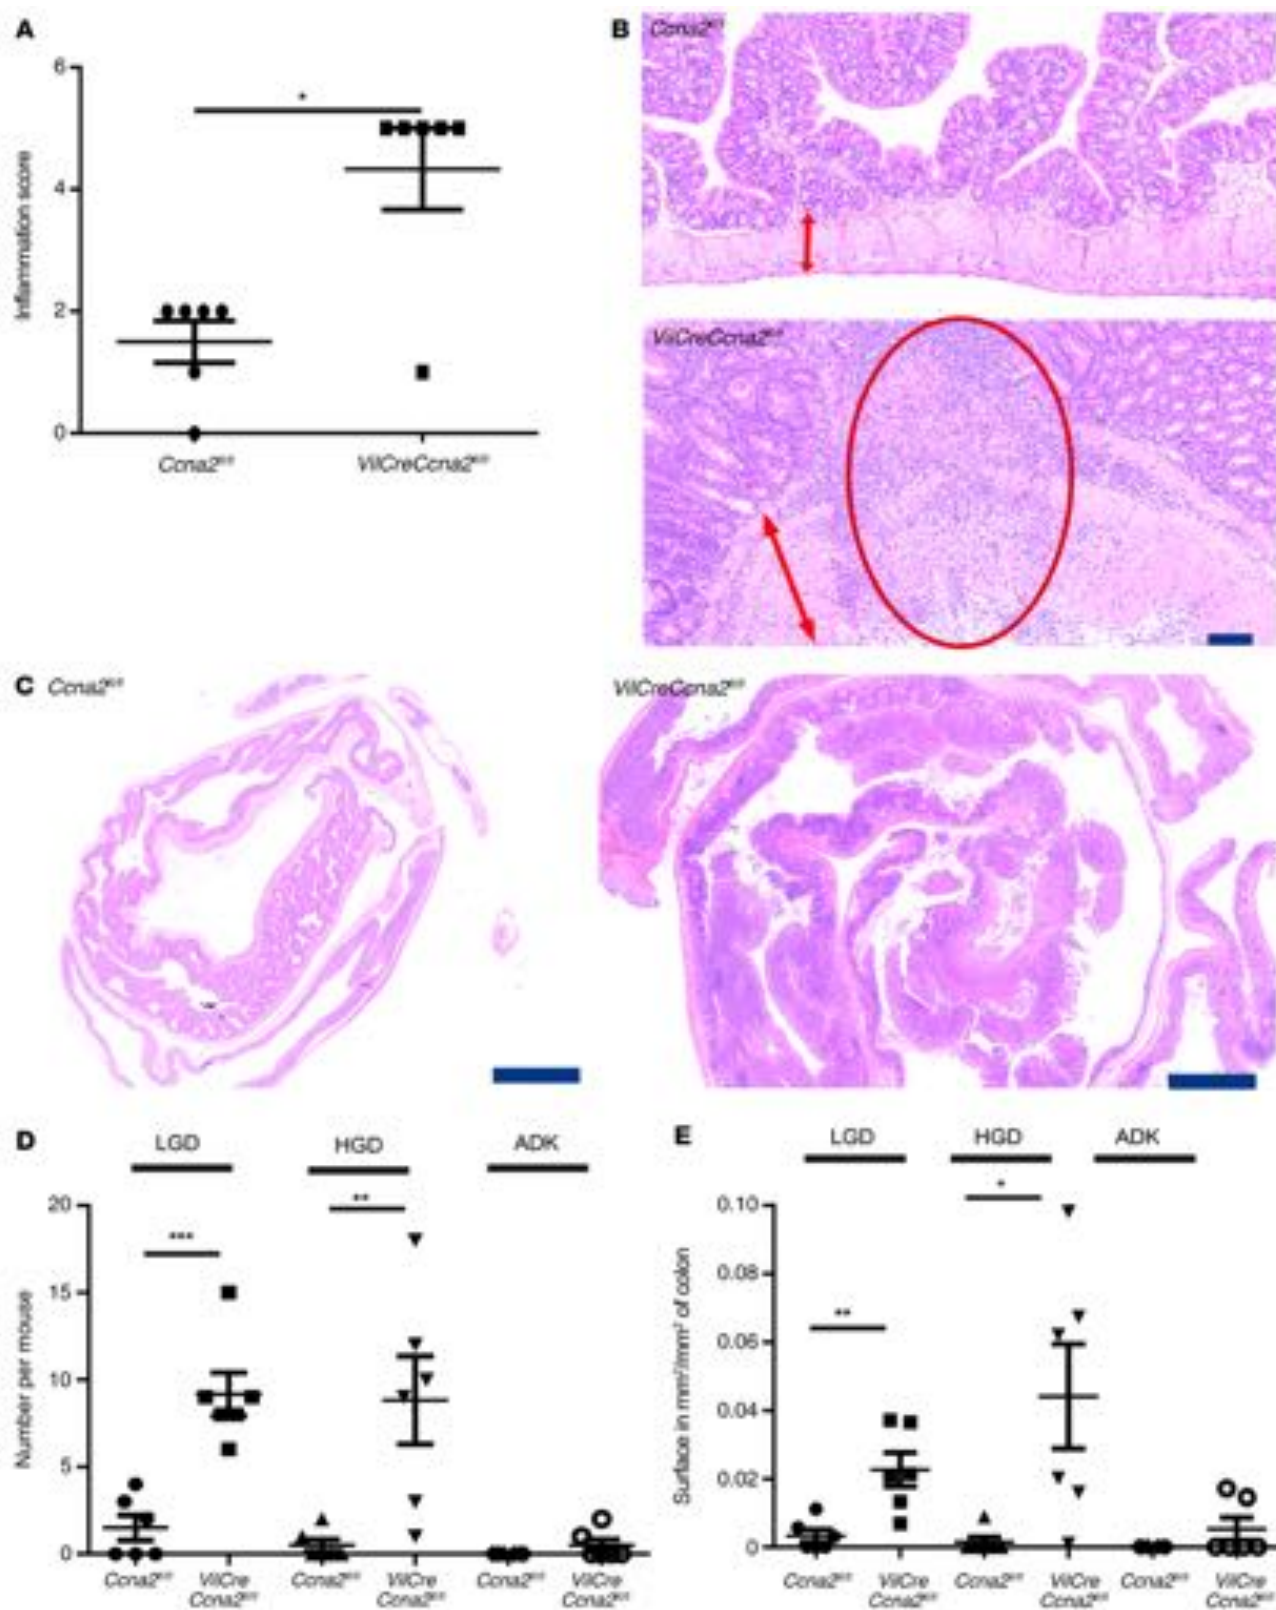

Figure 7. Cyclin A2-deficient mice are more susceptible to CAC. *Ccna2^{fl/fl}* ($n = 6$) and *VilCre Ccna2^{fl/fl}* ($n = 7$) mice were subjected to a modified AOM/DSS protocol including only 1 DSS treatment (Supplemental Figure 6A). (**A** and **B**) Quantification of the inflammatory scores for colons from control and *VilCre Ccna2^{fl/fl}* mice (**A**) and representative H&E stainings showing transmurial immune cell infiltration (indicated by the red oval) in KO mice (**B**) (the red arrows mark the muscularis mucosa). Scale bar: 100 μm . (**C**) Representative images of H&E-stained colons from control and cyclin A2-deficient mice subjected to the CAC protocol. Scale bars: 2 mm. (**D** and **E**) Number of dysplasia (LGD, HGD) and adenocarcinoma (ADK) occurrences per mouse and dysplasia and adenocarcinoma area expressed in mm^2/mm^2 of colon in control and *VilCre Ccna2^{fl/fl}* mice. Data represent the mean \pm SEM. * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$, by unpaired, 2-tailed Student's t test.

Figure 8. Lesions in colons from cyclin A2-deficient mice exposed to CAC display elevated levels of active β -catenin, DNA damage, and IL-6 expression. Representative immunostainings for active β -catenin, γ H2AX, and IL-6 in morphologically similar lesions in colons from control and cyclin A2-deficient mice at the end of the AOM/DSS protocol described in Supplemental Figure 10A. Scale bars: 100 μ m. Original magnification, $\times 1.5$ (enlarged insets).

Inhibitor Tabs (MilliporeSigma). The supernatant was collected as the nucleoplasmic fraction after centrifugation (16.1 rcf, 5 min).

Western blot analysis. Protein samples were prepared in 4 \times Laemmli buffer, separated in sodium dodecyl sulfate-polyacrylamide gels, and electro blotted onto nitrocellulose membranes (MilliporeSigma) using a wet/tank transfer system (Bio-Rad). The antibodies used for Western blotting in this study are listed in Supplemental Table 10. All the experiments were performed at least 3 times in triplicate. Quantification of immunoblots was carried out using ImageJ. Experimental

values are expressed as the ratio of protein levels versus control with the TFIIB and histone H3 signal for the nucleoplasmic fraction. The complete unedited blots are shown in the supplemental material.

Colon organoids. Colons were washed extensively in cold PBS and penicillin-streptomycin and then cut into 0.5 cm pieces, which were placed into a 50 mL tube containing 10 mL cold PBS. The pieces were washed 5 to 10 times with cold PBS supplemented with antibiotics and then incubated in PBS and 25 mM EDTA on a roller for 30 minutes at 4°C. After sedimentation, the pieces were successively washed 4 times

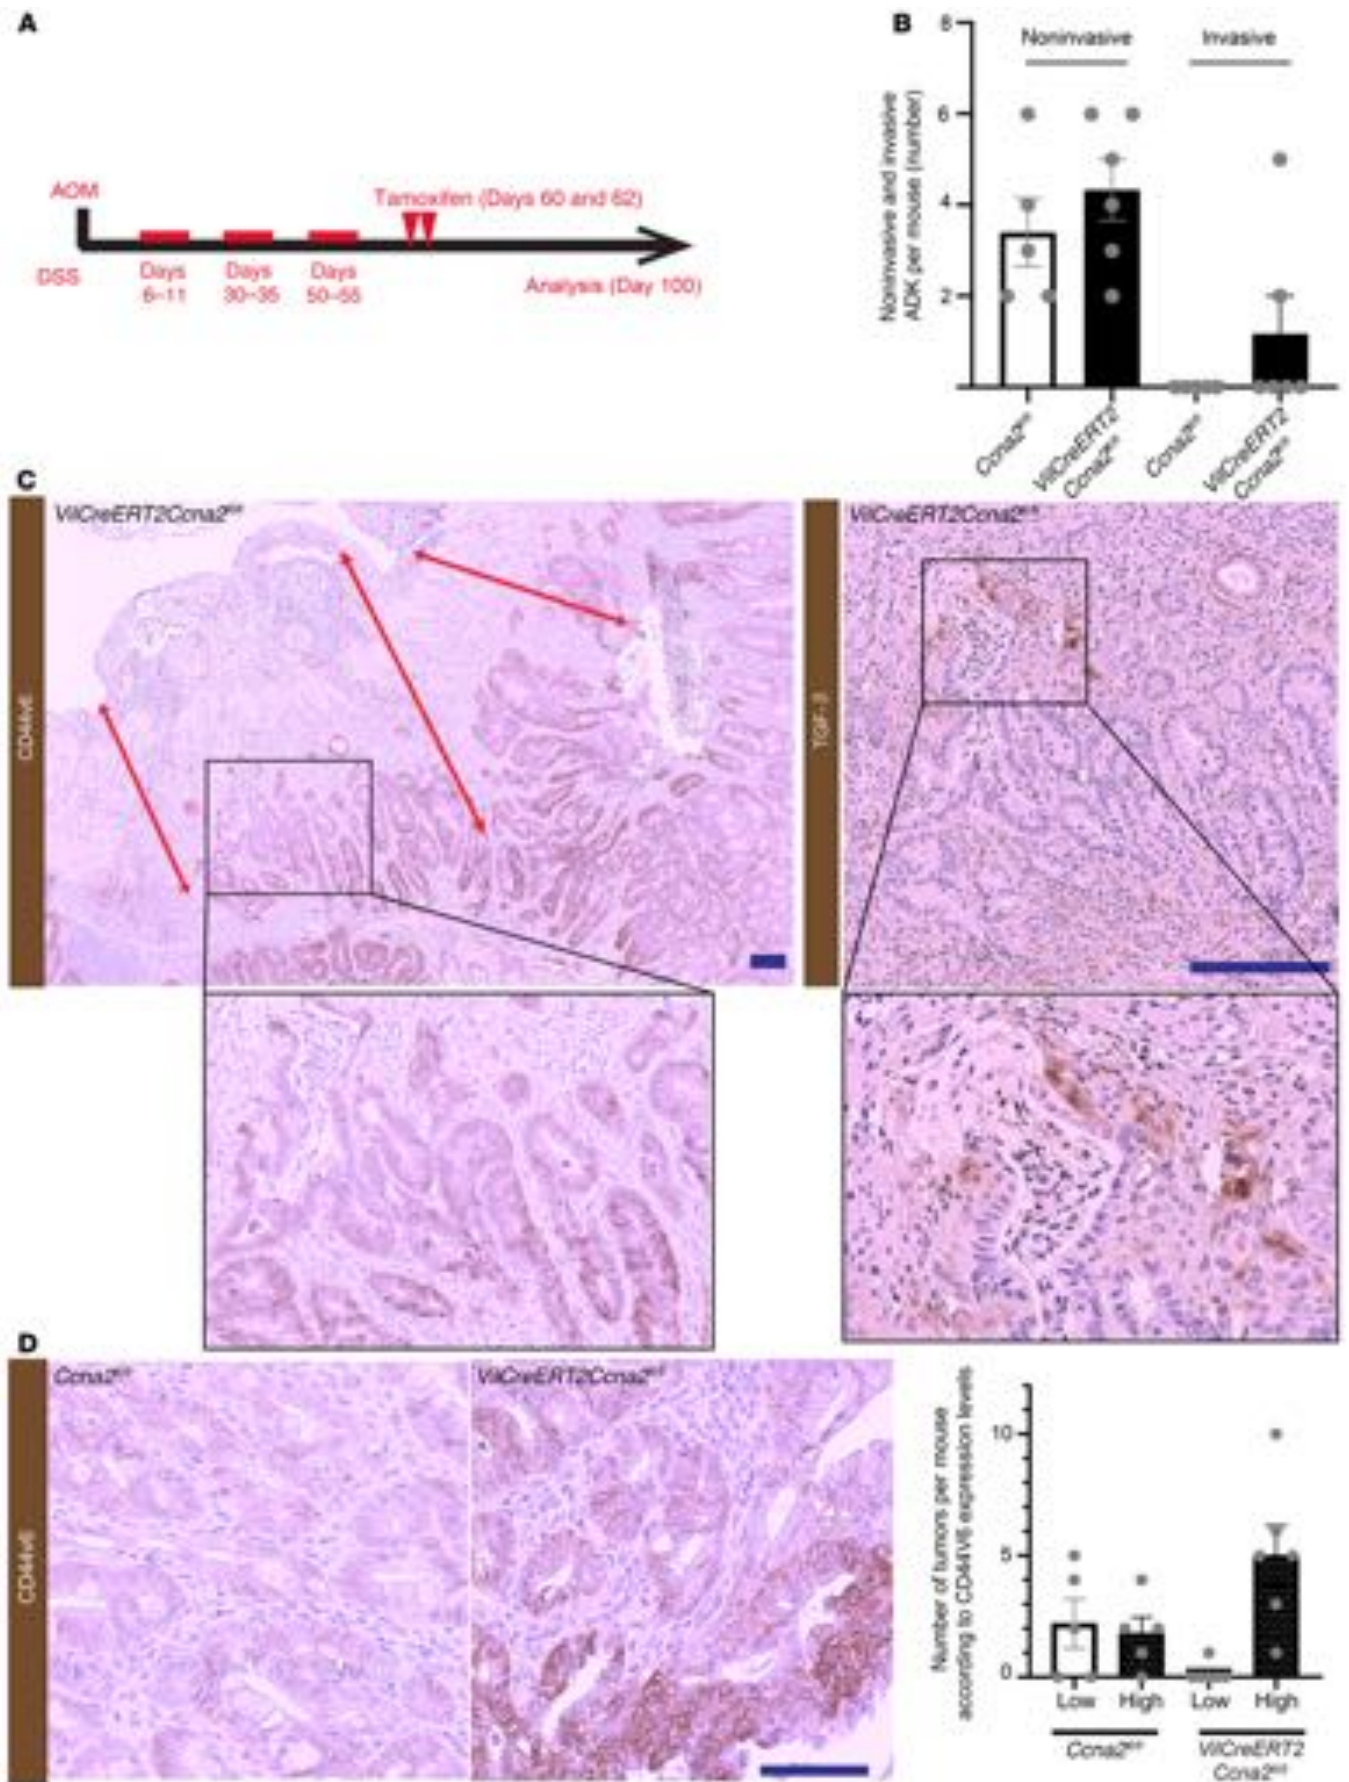

Figure 9. Inactivation of cyclin A2 on established tumor lesions leads to invasive adenocarcinomas. (A) Schematic representation of the AOM/DSS protocol applied to *VilCreERT2 Ccna2^{fl/fl}* ($n = 8$) and control ($n = 8$) mice. Note that cyclin A2 deletion was induced by tamoxifen injection after the last DSS treatment. (B) Quantification of the number of noninvasive versus invasive adenocarcinomas per mouse for control (*Ccna2^{fl/fl}*) and cyclin A2-deficient (*VilCreERT2 Ccna2^{fl/fl}*) mice ($n = 8$ each). (C) Representative images of an invasive adenocarcinoma disrupting the muscularis mucosa and infiltrating through the muscularis propria, as indicated by red lines. The panel on the left shows an immunostain for CD44v6 in tumor cells, and the panel on the right shows a focal immunostain for TGF- β in the desmoplastic stroma surrounding the tumor cells. Scale bars: 100 μ m. Original magnification, $\times 3$ (enlarged insets). (D) Representative images of immunostains for CD44v6 on tumors of control and cyclin A2-deficient mice and corresponding quantification of low and high CD44v6-expressing tumors. Tumors were classified as low expressers when less than 50% of the area had detectable CD44v6 expression. Scale bar: 100 μ m. Data represent the mean \pm SEM.

in 10 mL cold PBS. The supernatant for each wash was strained in a 70 μ m mesh filter, and each fraction (F1-F4) was centrifuged at 600g for 5 minutes and checked under the microscope for the presence of well-formed crypts. In most cases, fractions 3 and 4 were used for the organoid culture. A total of 200 crypts were resuspended in 50 μ L Matrigel in either WENR media for the *Ccna2^{fl/fl}* and *VilCre Ccna2^{fl/fl}* crypts or ENR media for the *VilCre Ccna2^{fl/fl}* crypts (Supplemental Table 11) and microscopically inspected once a day.

RNA-Seq sample preparation and bioinformatics analysis. CECs were isolated from the proximal colons of 4-week-old *Ccna2^{fl/fl} VilCre* (KO) and *Ccna2^{fl/fl}* (control) mice, as described above. RNA was extracted using the Roche High Pure RNA Isolation Kit (Roche Molecular Systems), and purity as well as integrity were controlled using the Agilent RNA 6000 Nano Kit (Agilent Technologies). RNA-Seq was performed on an Illumina NextSeq 500 platform. Quantification of the gene transcripts was performed using the Kallisto program (63), which is based on the pseudoalignment principle, with default settings. GRCm38 RefSeq was used to annotate the transcripts. We used the STAR program (64) to align the reads on the *Mus musculus* reference genome (GRCm38/mm10). Raw data are available in the NCBI's Gene Expression Omnibus (GEO) database (GEO GSE149716; <https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE149716>). For differential expression analysis (DEA), we first filtered the transcripts with too-low counts among the samples using the *filterByExpr* function of edgeR, with default settings. To perform the data normalization and DEA of *Ccna2*-deficient versus control samples, we ran standard steps of edgeR and DESeq2 in parallel on the filtered data. For both DEA methods, we applied a cutoff threshold of 0.05 to the adjusted *P* values and a cutoff threshold of 2 for the fold changes. The 2 resulting lists of significantly differentially expressed genes were intersected. We separated the upregulated and downregulated genes on this unique list. Finally, to perform functional enrichment analysis, these sublists were submitted to the dedicated function of the clusterProfiler package, available on Bioconductor (<https://bioconductor.org/packages/release/bioc/html/clusterProfiler.html>). A Fisher's exact or χ^2 test was used when appropriate to analyze the enrichment of the *CCNA2* signature with the published signatures of interest.

CAC. For induction of CAC in the *VilCre Ccna2^{fl/fl}* mice and their corresponding controls, mice were intraperitoneally injected with 6.25 mg/kg AOM (MilliporeSigma). Mice were treated with one 5-day cycle

of 1.75% (w/v) DSS (TdB Consultancy AB) in the drinking water on day 5 of the protocol. Mouse weights were checked every 2 days for 2 months, except for the week following the DSS treatment, when the weight was measured every day. Mice were then sacrificed and colons prepared for histological analysis after fixation in 10% formalin. Tissues were embedded in paraffin, and sections were stained with H&E or incubated with primary antibodies (anti-active β -catenin, anti- γ H2AX, and anti-IL-6), as reported above. Colitis was scored as outlined in Supplemental Table 3. For induction of CAC in the *VilCreERT2 Ccna2^{fl/fl}* mice and their controls, mice were injected as described above with AOM but were treated 3 times with 1.75% DSS in the drinking water for 5 days on days 6, 30, and 50 of the protocol. Tamoxifen intraperitoneal injection was performed on days 63 and 65 to induce cyclin A2 inactivation, and mice were sacrificed on day 100 for analysis.

Patient samples. Details of the TMA generated at Centre de Ressources de l'Institut Régional du Cancer de Montpellier (CRB-ICM) (agreement number BB-033-00059) in Montpellier, France, are listed in Supplemental Table 6. Some tissue samples were generated as duplicates from the same patients but were considered individual templates for the statistical analysis because of tumor heterogeneity.

For the transcriptome meta-analysis, we collected clinicopathological and gene expression data on tissues from NC, pCRC, and metastatic CRC (mCRC) samples from 10 public data sets and 1 data set generated at the Institut Paoli Calmettes (Marseille, France) comprising at least 1 probe set representing *CCNA2*. Sets and raw data were collected from the NCBI's GenBank and GEO, ArrayExpress, and TCGA databases (Supplemental Table 4). Samples were profiled using whole-genome DNA microarrays (Affymetrix) or RNA-Seq (Illumina). The analyzed data set contained a total of 2401 samples, including 95 NC samples, 2239 pCRC samples, and the 67 mCRC samples included in the present analysis, which were obtained from liver ($n = 47$) and lung ($n = 20$).

Gene expression data analysis. Data analysis required a step of preanalytic processing. We first normalized each data set separately using the robust multi-array average (RMA) (65) with the nonparametric quantile algorithm for the raw Affymetrix data. Normalization was done in R using Bioconductor and associated packages. We then mapped hybridization probes across the different microarrays represented as previously reported (66). When multiple probes mapped to the same GeneID, the one with the highest variance in each data set was retained. The available TCGA RNA-Seq data that were already normalized were \log_2 transformed. Next, *CCNA2* mRNA expression data were extracted and the batch effects corrected through the 11 studies using *z* score normalization. Briefly, for each expression value in each separate study, *CCNA2* values were transformed by subtracting the mean of the gene in that data set divided by its SD, measuring the mean and SD of primary samples. *CCNA2* expression was measured as a discrete value after comparison with median expression in the 95 NC samples; upregulation, thereafter designated *CCNA2^{hi}*, was defined by a CRC/NC ratio of 2 or higher, and no upregulation (*CCNA2^{non-hi}*) by a CRC/NC ratio below 2. The CMS classification (8) was based on the CMScaller tool made by Eide et al. (67). Finally, to explore the biological pathways associated with our *CCNA2*-based classification, a supervised analysis was applied using learning and validation sets. The learning set included the 459 samples of TCGA data set that included 222 *CCNA2^{non-hi}* and 237 *CCNA2^{hi}* samples. A moderated Student's *t* test with empirical Bayes statistic included in the limma R packages was used. The FDR (68) was applied to correct

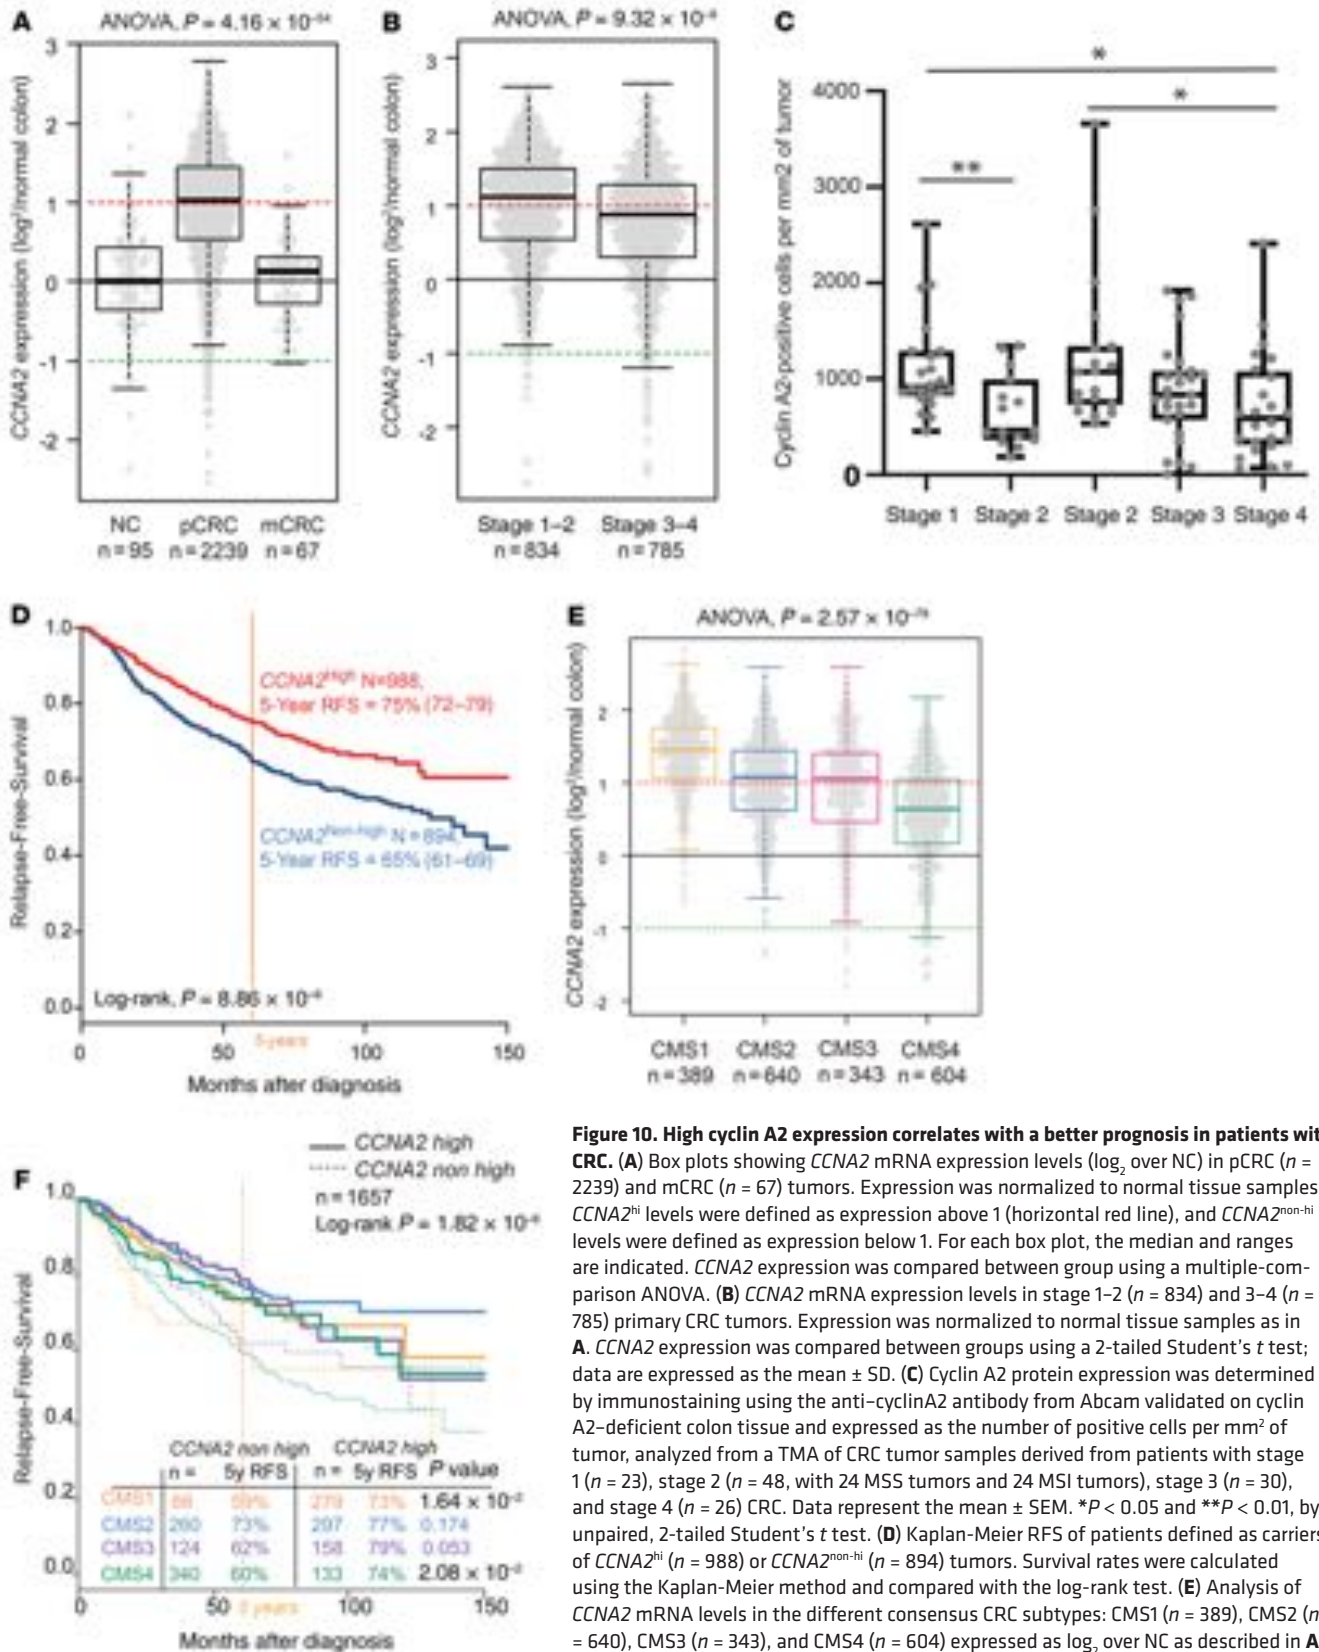

Figure 10. High cyclin A2 expression correlates with a better prognosis in patients with CRC. (A) Box plots showing *CCNA2* mRNA expression levels (\log_2 over NC) in pCRC ($n = 2239$) and mCRC ($n = 67$) tumors. Expression was normalized to normal tissue samples. *CCNA2*^{hi} levels were defined as expression above 1 (horizontal red line), and *CCNA2*^{non-hi} levels were defined as expression below 1. For each box plot, the median and ranges are indicated. *CCNA2* expression was compared between groups using a multiple-comparison ANOVA. (B) *CCNA2* mRNA expression levels in stage 1-2 ($n = 834$) and 3-4 ($n = 785$) primary CRC tumors. Expression was normalized to normal tissue samples as in A. *CCNA2* expression was compared between groups using a 2-tailed Student's *t* test; data are expressed as the mean \pm SD. (C) Cyclin A2 protein expression was determined by immunostaining using the anti-cyclinA2 antibody from Abcam validated on cyclin A2-deficient colon tissue and expressed as the number of positive cells per mm² of tumor, analyzed from a TMA of CRC tumor samples derived from patients with stage 1 ($n = 23$), stage 2 ($n = 48$, with 24 MSS tumors and 24 MSI tumors), stage 3 ($n = 30$), and stage 4 ($n = 26$) CRC. Data represent the mean \pm SEM. * $P < 0.05$ and ** $P < 0.01$, by unpaired, 2-tailed Student's *t* test. (D) Kaplan-Meier RFS of patients defined as carriers of *CCNA2*^{hi} ($n = 988$) or *CCNA2*^{non-hi} ($n = 894$) tumors. Survival rates were calculated using the Kaplan-Meier method and compared with the log-rank test. (E) Analysis of *CCNA2* mRNA levels in the different consensus CRC subtypes: CMS1 ($n = 389$), CMS2 ($n = 640$), CMS3 ($n = 343$), and CMS4 ($n = 604$) expressed as \log_2 over NC as described in A (multiple-comparison ANOVA). (F) Kaplan-Meier RFS curves for all patients with pCRC according to both the *CCNA2*-based classification (*CCNA2*^{hi} and *CCNA2*^{non-hi} classes with the solid curves and dashed curves, respectively) and CMS subtypes.

the multiple testing hypothesis, and significant genes were defined by the following thresholds: a *P* value of less than 5%, a *q* value of less than 25%, and a fold change of greater than 2. The resulting GES was based on a metagene score defined as the difference between the mean expression of genes upregulated and the mean expression of genes downregulated in the *CCNA2*^{hi} samples, using a cutoff of 0. This score was then applied to both learning and validation sets to test the robustness of the GES (Student's *t* test). Gene ontology (GO) analysis of the gene list was based on GO biological processes of the Database for Annotation, Visualization, and Integrated Discovery (DAVID) (<http://david.abcc.ncifcrf.gov/>).

Statistics. Correlations between the *CCNA2* expression-based classes (non-high versus high) and the clinicopathological factors were calculated using the Fisher's exact test for binary variables and the Student's *t* test for continuous variables. Our primary endpoint, RFS, was calculated from the date of diagnosis until the date of metastatic relapse or death from CRC. The follow-up was measured from the date of diagnosis to the date of last news for event-free patients. Survival was calculated using the Kaplan-Meier method, and curves were compared with the log-rank test. Univariate and multivariate analyses were done using Cox regression analysis (Wald's test). The variables tested in univariate analysis included the *CCNA2*-based classification (non-high versus high), patients' age and sex, tumor location, pathological stage and grade, MMR status, and CMS classification. Multivariate analysis incorporated all variables with a *P* value below 5% in univariate analysis. All statistical tests were 2 sided at a 5% level of significance. Statistical analysis was done using the survival package (version 2.30) in R software (version 2.15.2). This article was written in accordance with reporting recommendations for tumor marker prognostic studies criteria (REMARK) (69). Statistical analysis of quantifications in the mouse study was performed using GraphPad Prism (GraphPad Software). An unpaired, 2-tailed Student's *t* test was used, except for nuclear size distribution, for which the Kolmogorov-Smirnov test was performed using R software.

Study approval. Mouse experiments were performed in accordance with the European Community guidelines (86/609/EEC) and the French National Committee (87/848) for the care and use of laboratory animals and were approved by the regional ethics committee

for animal experimentation in Languedoc Roussillon (APAFIS no. 18685-2019012817242507 v3; reference no. O1556.02)

Author contributions

YG, MG, CP, VP, RT, HT, C. Longobardi, JB, CM, QDC, PF, FBM, BR, C. Lemmers, IZ, KC, SG, RA, EM, and BL conducted experiments and acquired and analyzed data. EM, BL, and MH designed research studies and analyzed data. YG, FB, JMB, JT, PS, EM, BL, and MH wrote the manuscript. MH is the principal investigator and managed the mouse experiments. BL was a lead scientist and managed the experiments involving mice. EM was a collaborating scientist and managed experiments involving human samples. For co-first authorship order assignment, YG was involved earlier on in the project, and MG was involved in the revision of the manuscript.

Acknowledgments

We are grateful for the assistance of the RIO imaging platform, the RHEM and RAM histology and animal experimentation platforms, as well as the IGMM mouse facility in Montpellier. We thank Thierry Gostan for his help with statistical analysis, Ula Hibner for careful reading of the manuscript, and Jan Paul Medema and Susana Prieto for help with establishing organoid cultures. We are grateful to Maguy Del Rio for her help with *CCNA2* mRNA expression analysis in patients. The authors acknowledge the Biological Resources Center from the L'Institut du Cancer de Montpellier (ICM) (ICM Biobank number BB 0033 00059). This work was supported by INCA (project 2013-111) and a Site de Recherche Intégrée sur le Cancer (SIRIC) Montpellier Cancer Grant (INCa_Inserm_DGOS_12553 and La Ligue contre le Cancer - Comité 34, to BL). Computing resources for this study were provided by the Datacenter IT and Scientific Computing (DISC) facilities of the Cancer Research Center of Marseille.
